A major barrier to using public transport is the cost. Where it is provided at reduced rate for older people or indeed for free to older people, an increase in use and in satisfaction is found. In the United Kingdom, around 60% of older people reported an increase in their bus use due to free travel being introduced for older people (Baker and White 2010; Mackett, 2013a, 2013b). In addition, around 74% of respondents stated having a pass enabled them to visit new places and to engage in new leisure pursuits. Andrews (2011) found that 74% of his respondents thought their free bus pass improved their quality of life. Dargay et al. (2010) modeled bus use against what would have happened if no free bus pass had been introduced and suggests the number of bus stages (groups of bus stops) traveled through by older people increased by 45.4% in rural areas and 26.5% in urban areas. While becoming eligible for a free bus pass is associated with increased use of public transport (Webb et al., 2011), this has not reduced the amount of driving among the older population, though it is worth noting that driving may have increased even more without free bus travel.

The driver of the bus can make or break journeys for older people. An awareness of older people's issues is needed. A major concern noted in studies across the world was that the driver drove away from the bus stop before the older person had sat down, or it was missing the older person's stop and the older person then having to walk much further than anticipated (Broome et al., 2010; Musselwhite, 2018c; Transport for London, 2009, 2013). Age UK London (2011) surveyed bus driving behavior and, across 550 journeys, found that in 42% of cases passengers were not given enough time to sit down before the bus was driven away from the stop and in 25% of the cases the bus did not pull up tight to the kerb at the bus stop. Gilhooly et al. (2002) note a major barrier being personal safety and security, especially in the evening and at night. Again this is an issue found globally. Buses in high-income countries are usually bound by regulation to make them accessible, with lowering floors to ease entry and exit and grab rails to help maneuver inside the bus, along with standards of information provision and lighting, all which help older people. However, these standards are not the case in many other countries, making the use of public transport dangerous for older people, or excluding them altogether (Broome et al., 2010).

Bus services often tend to be poorer in rural communities, with few buses or in some cases no buses at all. Even in urban areas buses often tend to follow radial routes into the city center, which favors workers' patterns of travel. Older people are just as likely to travel between intraurban across cities to access the services and shops they want to (Musselwhite and Curl, 2018).

Train Travel

There is not much research on train travel among older people. Use of railways tends to decline in later life, mostly because the necessity to use railways for commuting or work declines. However, rail travel could provide an excellent way to travel long distances for older people.

Previous research has also highlighted issues with overcrowding on stations and platforms as a particular issue for older people (Gilhooly et al., 2002). In addition, ticketing can be confusing, leading to anxiety, or older people failing to get the cheapest or even the correct ticket (Musselwhite, 2011). Stations themselves can also appear unsafe, especially if they do not have staff present at them (Cozens et al., 2004).

In the study of one train operating company in the United Kingdom, Musselwhite (2019) found older people were overrepresented in passenger accidents across the railway, and were especially overrepresented compared to other age groups in accidents boarding, slips, trips and falls on trains and slips, trips and falls at the station frontage, car park, and concourse. Audits reveal the need to see the railway station to train service as a continuous entity with better signage, lighting, and places to sit and rest throughout the station from frontage, to concourse, to platform, and to boarding the train. The areas from arriving at the station from other transport or in the car to the platform itself were often neglected spaces. To reduce accidents boarding more level access between platform and train is needed at standard.

Community Transport

As an alternative to conventional public bus services, in some countries there are specialist transport services, sometimes also known as community transport or transit, which operate more or less door to door for people who cannot access public or private transport. Services are often provided by a charity or a third sector organization, sometimes under license from local authorities. Such services can be the difference between staying in and going out (ECT, 2016). There are direct improvements on people's health through affording greater access to GP and hospital services and reductions in missed appointments, improvements in diagnosis, and therefore lower healthcare costs (ECT, 2016). It can also mean people are discharged earlier as they have access between hospital appointments and home (ECT, 2016). Importantly, drivers can act as informal carers and can help identify early warning signs of illness or of loneliness and isolation, as well as offering social support to the passengers (ECT, 2016).

However, there are some barriers to community transport use (Musselwhite, 2018c). Because services are very dependent on third sector and charity provision they can be somewhat fragmented across the country. They might be short-lived often existing around a particular one-off or small scale-funding offering and around key individuals. People who may well benefit from such a service can sometimes feel the service is not for people like them; there is sometimes the perception that it is for people with disabilities, rather than for everyone with accessibility issues (Musselwhite, 2018c). Frequently, there is a lack of information and, as a result, much misunderstanding of the service (Parkhurst et al., 2014; Ward et al., 2013). Journeys typically are based around providing transport to shops, services, and doctors and hospitals, but there needs to be more “discretionary” journeys provided to places of leisure and fun (Musselwhite, 2017b).

Taxis and Paratransit

To help people in many LMIC, motorcycle taxi services are found to transport people around, especially into congested and busy city centers. In some countries, this service is still too expensive for the majority of people to use. For example, in Tanzania many people cannot afford to use the motorcycle service as discussed by Porter et al. (2018). People in one district (Kilolo) would leave their village shortly around midnight to walk 5 hours to the bus stop to get the one bus per day into town. In another district (in Meru district) older people could not physically get onto a motorcycle or on to the back of a pickup to go to town (Porter et al., 2018).

In high-income countries, the uses of taxis are often seen as too expensive, so they are avoided or rationed and so only partly fulfill transport needs. There are concerns over the safety of modern paratransit services such as Uber and Lyft, with concerns over data being shared, safety of the ride itself, and regulation of drivers.

Governance, Policy, and Societal Norms

There is a tendency for older people to be ignored in transport policy and governance. This is because transport provision is driven largely by economic interests in most countries which results in provision around the working adult and inter- and intraurban mobility with a focus on provision in core work hours 9–5 (Musselwhite, 2018a). Older people are less likely to fit this pattern of work and where they work, they often work part time and avoid rush hour travel if they can. Even though there is scope for greater impact from policy if directed around life stages (e.g., retirement from work, becoming a grandparent, becoming a carer), age is very rarely mentioned in policy contexts (Avineri and Goodwin, 2010).

Conclusion

There is no quick fix solution to producing age-friendly transport solutions and making alternatives to the car more attractive. At the very top level, there is a need to recognize needs and issues older people have that are unique and have strategies, and plans in place to support the difficulty that older people have with transport. Multiple stakeholders often control public space and have different interests. There is a need to recognize that older people's mobility may fit different patterns than those that transport policies are usually formed around. They are less likely to be working, if they are more likely to be part time or have more flexible hours and they are less likely to be moving in interurban spaces. A comprehensive strategy bringing together the different stakeholder needs with a focus on aging is required. Overall, walking and cycling for older people must be given greater priority among decision-makers. Provision of services for older people needs to take these elements into account. Crucial to public and community transport use is a mix of people and infrastructure-based support. At the active travel level, infrastructure is crucial to support walking and cycling.

Introduction

In 1992, the European Union (EU) published a *Green Paper on the Impact of Transport on the Environment*.

'This Green Paper provid[ed] an assessment of the overall impact of transport on the environment and presents a Common strategy for 'sustainable mobility' which should enable transport to fulfil its economic and social role while containing its harmful effects on the environment.'

This paper responded to the challenges raised a few years earlier by the United Nations (UN) report *Our Common Future*. The *Green Paper* took aim at the rapidly increasing environmental impacts from the transport sector, and was a clear statement of transport policy in the EU. The *Green Paper* introduced the concept of 'sustainable mobility' to the international agenda—a bold but much needed appearance.

Bold in its acknowledgement of the intertwined and exceedingly complex relationship between transport's positive effects and its negative social and environmental impacts. Indeed, over the succeeding years, it has proven difficult to find a comfortable match between transport and sustainable development. It was *necessary* as it was (and still is) widely acknowledged that the increasingly negative impacts of transport were beginning to exceed the overall positive ones, that is, business-as-usual was unacceptable.

In 2015, the UN presented the 2030 Agenda for Sustainable Development comprising 17 Sustainable Development Goals (SDGs) and 169 targets—almost three decades after *Our Common Future* and the *Green Paper*. Again, this was another *bold* step. However, it is both striking and alarming that transport and its impacts are almost absent in the *2030 Agenda*. Admittedly, the *2030 Agenda* states that "we will adopt policies which increase [...] sustainable transport systems . . .," but is this helpful? SDG target 11.2 is somewhat more specific stating: "By 2030, provide access to safe, affordable, accessible and sustainable transport systems for all, improving road safety, notably by expanding public transport, with special attention to the needs of those in vulnerable situations, women, children, persons with disabilities and older persons." In summary, the SDG targets are diffuse and deal with transport at a very general level—and one strains to draw any clear conclusions as to how progress will be made towards the achievement of target 11.2.

This chapter is organized as follows; in the second section, the currently unsustainable status of the transport system will be presented. The third section outlines some of the dominant paths towards sustainable mobility. In the fourth section, we present some thoughts on further work.

Before we proceed, three clarifications are necessary. First, the terms "sustainable transport" and "sustainable mobility" can be found in the literature, and are often used synonymously. In North America "Sustainable transport" seems to be preferred, and in Europe "sustainable mobility." These terms embody both revealed- (actual- physical displacement) and potential (attribute of being mobile) mobility—in addition to entailing the same ideas and policy implications. As such, we acknowledge that- and use these terms interchangeably.

The second clarification emphasizes that this chapter focuses on *passenger* mobility in *developed* countries, since it is here that most of the resources are consumed, and pollution emitted. However, we acknowledge the importance of achieving sustainable- goods transport and mobility in developing countries. Additionally, the conclusions reached here are transferable to the freight sector, and with suitable adaptations for sustainable mobility in developing countries.

The third and final clarification states that this chapter focuses on the *environmental* imperatives associated with sustainable mobility, as these are the developed countries' main challenges. However, the equally important imperatives concerning needs and equal access to transport should not be forgotten, and the interpretations presented here should be relevant for the concerns of developing countries.

The number of books, articles and reports about sustainable mobility has increased steadily since 1992. This reflects the increasing unsustainability of the transport sector. A large and rich selection of literature now exists covering this field—and since projections forecast that the unsustainability of transport will continue to grow, the number of books, articles and reports is likely to increase too.

From a review of the academic literature, one can acknowledge that the mainstream understanding and interpretation of sustainable mobility has evolved since 1992, and can be grouped into four generations of studies. The first generation of studies spans the era 1992–93, and were both techno-centric and focused on how to limit transport’s negative environmental impacts by improving then-existing technology. The second, third, and fourth generations of studies span the eras 1993–2000, 2000–10, and 2010 present, respectively. These last three generations of studies, increasingly acknowledge the limitations of preceding efforts toward achieving sustainable mobility, and open for an increasingly greater diversity of alternatives. These generations of studies have become gradually more interdisciplinary in nature—reflecting the inter-relatedness of mobility with all other aspects of society.

An Unsustainable Transport System

Since the human migrations out of Africa millions of years ago, travel has been part of collective experience. Our motivation for traveling has varied, though for the most part, we have traveled to improve our lives. Whatever ones motivation, early travel was uncomfortable, dangerous and enormously time-consuming—today, some might argue that little has changed. However, there are two indisputable differences between past and present travel. First, in modern times we have experienced an extraordinary growth in mobility (measured in trips made and distance traveled), second, is the staggering increase in mobility’s associated environmental and social consequences.

Population growth in the 20th century was remarkable—with the world’s population increasing by a factor of 4. Growth in mobility was remarkable too—with motorized passenger kilometers and ton-kilometers by all modes growing by a factor of approximately 100 (e.g., [Fig. 1](#)). However, whereas population growth shows signs of leveling-off, growth in mobility does not—particularly, growth in mobility has been extensive the past half century. For example, in 1952, the average Norwegian traveled 5.5 km/day by motorized vehicle. In 2000, Norwegians’ traveled 48.7 km daily—and is every increasing into this century, with similar patterns visible in the rest of the developed world. Furthermore, comparisons of global scale—baseline (business-as-usual) scenarios foresee that this trend, particularly of increased travel by road-freight and air are likely to increase in the future.

While transport and mobility are acknowledged as important elements towards economic growth and accessibility, the negative social and environmental impacts of increased motorized mobility—particularly road and air travel—have been broadly acknowledged:

- Transport is a major consumer of energy and material resources, with around 31.6% of the world’s final energy consumption used for transport, mostly from nonrenewable energy resources.
- The production of motor vehicles requires large amounts of materials, for example, ferrous and nonferrous metals. Currently, in Organization for Economic Co-operation and Development (OECD) and non-OECD countries, motor vehicle production consumes 7% and 3% of ferrous metals respectively, this is similar for non ferrous. With demand for metals in both regions expected to grow by a factor of 2.2 and 3.5, respectively, between 2017 and 2060.

Figure 1 Passenger transport in Norway, 1900–2005. Nonmotorized and motorized transport. Source: [Holden \(2007\)](#).

- Transport is a major contributor to air-, soil- and water pollution at the local, regional, and global scale. For example, transport is currently the source of 24% of global CO₂ emissions.
- Despite the fact that transport networks and infrastructures cover only 3% of artificial land in Europe, its associated impacts can have dire consequences for biodiversity due to land fragmentation.
- Furthermore, annual casualties from road traffic are 1.35 million people worldwide, and cost most countries 3% of their GDP.
- Finally, access to mobility services is unevenly distributed, resulting inequality issues with respect to public and private services access and potentially social exclusion.

The previous points lead to diagnosing the mobility system as unsustainable. Furthermore, without major changes in mobility policies and practices, this unsustainability will continue well toward the end of this century.

Unfortunately, the persistence and complex nature of the transport system makes influencing mobility patterns difficult. The persistent nature lies in the fact contemporary investments in transport—both infrastructure for example, roads, bridges and airports, and vehicles, for example, cars, trains and planes—will influence mobility patterns long into the future. Thus, changes to the transport system and subsequently mobility patterns requires a long period.

The transport system is complex, and consist of three sub-systems that are interconnected. The first subsystem covers motorized means of transport. Here, sustainable mobility requires an evaluation of both the technology relating to the means of transport and the total distance traveled by each transport mode. In other words, claims of sustainability are not limited to artifacts such as vehicles but pertain to the level of mobility in society. The second subsystem covers transport infrastructure. Here, sustainable mobility requires an additional evaluation of all impacts incurred during construction, use, maintenance, and decommissioning for each mode of transport, including the energy and resources embedded in the infrastructure itself (e.g., concrete, asphalt, and control systems). The third subsystem covers the energy system; particularly those energy carriers used to propel the aforementioned modes of transport. Here, sustainable mobility requires a comparative evaluation of both conventional energy systems with possible improvements, and alternative energy systems—covering both modes of transport and infrastructure. In summary, assessing the sustainability of a transport system requires the long-term integrated assessment—including both positive and negative impacts—of all three subsystems.

A Typology for Achieving Sustainable Mobility

Sustainable mobility means being able to address three elements simultaneously. The first element focuses on *what* strategies are relevant, and the second focuses on *who* the agents are that could take the lead. We combine these first two elements, thus creating a matrix populated by paths (element 3) of *how sustainable mobility* can be achieved and which actions could be taken to achieve them. **Table 1** presents the aforementioned matrix; with *what* (rows), *who* (columns), and *how* (cells) elements. Combined, these rows, columns and cells provide a typology for sustainable mobility paths.

The simplicity of this matrix conceals the inevitable gaps and overlaps in practical policy between strategies, agents and paths. Nevertheless, each strategy, agent, and path reflects an important area of contemporary interest. Furthermore, this differentiation promotes understanding and facilitates analysis.

The Main Strategies

It is logical to think that we can achieve sustainable mobility if we: travel more efficiently, travel differently and/or travel less. From this, one can glean three main strategies for sustainable mobility, which are: efficiency-, alteration-, and reduction strategies (elaborated on below).

The efficiency strategy entails improving the sustainability of mobility through more efficient-novel technologies. Here, the concept of “technology” is used in a broad sense; it includes the use of both *hard*- and *soft* technology (e.g., vehicle technology and fuel shifts vs. information, trip linking, apps, and logistics). More efficient technologies can be implemented in three parts of the transport system, that is, modes, infrastructure, and energy system.

Table 1 A typology of sustainable mobility paths

		<i>Agents (Who?)</i>		
		<i>The experts</i>	<i>The people</i>	<i>The firms</i>
Strategy (What?)	Efficiency (Improve)	“The green government”	“The green purchaser”	“The clean vehicles”
	Alteration (Shift)	“The public transport provider”	“The responsible traveler”	“The shared mobility schemes”
	Reduction (Avoid)	“The compact city”	“The essential life”	“The traveling electrons”

Source: Holden et al. (2020)

The *alteration strategy* entails the implementation of modal shifts to change existing transport patterns. Currently, cars and planes dominated the prevailing transport patterns; and the necessary shift is towards more collective, affordable and well-functioning forms of transport, namely public transport, for example, buses, trains, and trams, along with increased shared mobility, walking and cycling. An added benefit of which is that many of these alternative forms are more energy efficient than cars and planes. Furthermore, an affordable and well-functioning (public)-transport system increases accessibility for low-mobility groups.

The *reduction strategy* does not diminish the roles of the efficiency and alteration strategies—which both result in cuts to energy consumption and emissions. However, these cuts are not sufficient on their own to achieve sustainable mobility. Moreover, expected growth in transport demand can negate these reductions achieved by the first two strategies alone. Thus, a collective strategy must be formulated which includes an absolute *reduction* in motorized travel—which at the same time allows for those whose basic transport needs are not yet met to do so. Such *reductions* can be achieved by traveling less and/or performing shorter trips, for example, from compact land-use planning, increased internet shopping and telecommuting, and changing established travel preferences.

The Main Agents

The aforementioned strategy for achieving sustainable mobility is imperative, but someone (an agent) must take the lead in enacting the strategy (or strategies). It should be noted that no single agent may have either the responsibility or the possibility of implementing a particular strategy alone. Instead, finding strategic alliances and alignment of interests between agents is more likely. Thus, several agents at all levels should contribute, including national and local authorities, small and large companies, and the public. Though—with this said—someone must *take the lead*, notably key agents possessing the necessary powers (and resources) to implement the first steps driving the changes forward. These key agents can be classified into three main groups:

The experts: Politicians (doing politics) and their bureaucrats (implementing policies) populate the first group—these experts put administrative rationalism at the forefront. In this group, a close collaboration between science, professional administration, and a hierarchical bureaucratic structure forms the foundation for implementation. Here, the experts' solutions and the bureaucrat's implementation of these solutions trump the potentially preferred solutions of the *people* and *firms*—the two remaining groups. These experts draw on the collective experiences of established institutions, instruments and practices, such as regulatory agencies and policy instruments, environmental assessment, expert advisory commissions, policy analysis techniques, and public R&D programs.

The people: The second group is the people exercising democratic pragmatism at the forefront. While the previous group (*experts*) offers a top-down approach, the *people* promote a bottom-up approach, recognizing conditions such as learning, trial-and-error, and incremental progress toward achieving their strateg(y/ies). The *people's* democratic pragmatism is grounded on dialogue between networks of local agents, for example, local officials, nongovernmental organizations, lobbyists, activists, journalists, corporations, and international organizations; as opposed to administrative rationalism which is based on central leadership and hierarchy. The *people* draw on devices such as public consultation, alternative dispute resolution, policy dialogue, lay citizen deliberation, public inquiries, right-to-know legislation, and the power of social movements.

The firms: The third group (*firms*) embrace market mechanisms based on voluntary transactions between sometimes competing players towards achieving their sustainable mobility strategies. Good solutions offered by such markets can often be overlooked by administrative rationalism and democratic pragmatism that are based on political or social priorities respectively. It should be noted that the *firm's* relationship to administrative rationalism is twofold; hardline economic rationalists would prefer to minimize the role of the authorities, introduce private property rights (incl. natural resources and pollution), and place transactions between market actors at the forefront. More moderate economic rationalists acknowledge that authorities should *design*—or create even—markets through the use of financial instruments, thus authoring the rules to which market transactions must comply. Negotiable quotas, green taxes, fines, and incentives are some of the instruments the authorities can implement to provide for a favorable market. Here, economic rationalism appeals to the consumer, whereas democratic pragmatism appeals to the citizen. Consumers can use their influence in choosing environmentally friendly products and solutions, thus inadvertently influencing those products and solutions that on-offer by firms. In such a market, it is the most environmental-friendly firms who will prosper.

The Sustainable Mobility Paths

Derived from these three main strategies (*efficiency, alteration, and reduction*), and the three main agents (*experts, people and firms*), we derive nine sustainable mobility paths—presented in **Table 1** and the forthcoming text. Unavoidably, some will claim that other/additional paths have lost our attention, and it is likely that others would propose an alternate design for identifying these paths. Nevertheless, we argue that the paths presented here are firmly anchored in basic concepts from which any discussion of sustainable mobility can venture. Furthermore, the paths presented here cover the range of ideas found in the literature – building on a single strategy and one agent, these are:

The green government (1): Here, a top-down approach by governing bodies at national, regional or local level who impose regulations and standards or taxes and subsidies on the existing modes of mobility is suggested. This embodies the most frequent contemporary approach focused on emission control (e.g., European Emission Standards and the Motor Vehicle Air Pollution Control Act (Clean Air Act)), though would also include subsidizing of technology that is more efficient.

The green purchaser (2): Here, new- greener and efficient technologies are introduced to fulfill the demands of an informed, but slightly hesitant population. Hesitant, since the green purchaser does not necessarily wish to sacrifice their travel habits for a more

sustainable mobility system. Accordingly, the green purchaser seeks cleaner- more efficient options, as opposed to alternatives or reducing their travel. Some examples of this path include the proliferation of EVs in affluent areas, and voluntary carbon offsets for air travel.

The clean vehicles (3): Companies take the lead role towards achieving sustainable mobility in this path. These companies can range from the opportunistic (i.e., bidding to appease regulatory bodies and/or appeal to individual's green ambitions) to the altruistic. As opposed to throwing existing business models out the window—in this path—safe-incremental improvements are implemented towards cleaning existing vehicle technology (e.g., 83 and 276).

The public transport provider (4): Here, governments at the national, regional and local levels provide the basic infrastructure- and services for collective transport – opting to own and operate such services themselves, or purchasing these services from private companies. Additive to this is the government's promotion of public transport and discouragement of private vehicle use. For such governments, several instruments are available including: subsidizing travel fares by public transport, dedicating lanes for public transport, and tolling private cars in specific areas.

The responsible traveler (5): As opposed to the *green purchaser* path, here, the population is both informed and willing to choose more sustainable alternatives for mobility, that is, exchanging old mobility habits for new routines (e.g., bicycling instead of driving). These slight modifications in lifestyle do not come at the expense of satisfy general *needs* and *wants* involving mobility, and are often accompanied with added benefits (e.g., health). These decisions in some instances, are part of a grassroots innovation where bottom-up solutions are developed by activists and organizations responding to the interests and values of the community.

The shared mobility schemes (6): Here, the companies at the forefront are those who introduce disruptive technologies, that is, technologies that significantly alter the prevailing mobility system. This is as opposed to path three (clean vehicles) and it's incremental improvements to existing vehicle technology. These can be either intra- or intermodal disruptions, or as completely novel modes. Uber's introduction of car sharing, and autonomous road vehicles are examples of the former, and drone delivery vehicles the latter.

The compact city (7): As the name suggests, this path proposes a high-density built environment and intensification of activities, efficient land-use planning, and diverse and mixed land uses, with clear (non sprawling) boundaries. Here, transportation systems are efficient and rely primarily on public- and active forms of transportation (e.g., cycling and walking) made possible by shorter trip lengths—and which are often more attractive and desirable. As such, the compact city seeks to increase quality of life in its city quarters, (re-) devoting road space to urban parks, cafés and stores.

The essential life (8): The changes in lifestyle incurred by the population in this path are much deeper than the previous two (paths 2 and 5), and requires a transformation in how we define and fulfil *needs*. Here, the population must consider the full scope of Sustainable Development Goals and their perspectives on sociality, equity, work, and environment. The essential life requires extending the current 'local' trend to new dimensions—both in breadth (e.g., entertainment and tourism) and depth (e.g., the low carbon economy, or the 'tight' circular economy). Digital solutions will allow us to remain global citizens.

The traveling electrons (9): Here, allowing electrons to travel instead of people is made possible by information and communications technologies. In other words, telecommuting, the use of video conferences, and exchanging all types of information on the internet reduces people's need for physical travel. Despite studies showing the large embedded energy use and emissions associated with the necessary infrastructure, and the potential need (and want) to increase travel resulting from greater access to information and communication technologies, this is nevertheless a path which bears the *potential* to offer great reductions in energy use and emissions.

Concluding Remarks

The nine paths presented in this chapter outline the dominant paths towards achieving sustainable mobility. They introduce key elements into the sustainable mobility debate, and emphasize the plethora of strategies and agents involved. Individually, they are unlikely to make a real difference, and it is only in combination that a truly sustainable mobility system can be realized. Future work on these paths must include three steps.

First, this is a conceptual review of sustainable mobility paths. Thus, we do not provide detailed descriptions of how to achieve a sustainable energy system. Such descriptions must be accompanied with a set of concrete action in terms of governmental means and policies, individual behavior changes, and new business models and strategies. Still, choosing paths is important because they form and legitimize policy and behavior, and can create the necessary momentum for political movement and behavior change.

Second, each path must be empirically assessed against its credibility. There are three criteria by which paths must be assessed: their feasibility (are they possible?), acceptability (do we approve them?), and centrality (do they deliver sustainability?). All criteria are crucial. On one hand, a path that delivers sustainability but is neither feasible nor acceptable is of little help. On the other hand, a path that is feasible and acceptable, but fails to deliver sustainability is of little use.

Third, we need to study the relationship between the paths. They can be complementary (each focusing on different aspects of sustainable development), competing (each claiming to be the best solution to a particular aspect), and substitutional (each reducing the prospect of the other). They all belong, however, to the wider set of narratives that make up the sustainable energy literature and therefore deserve attention here.

Biography

Erling Holden is a professor in Renewable Energy at the Norwegian University of Life Sciences, and professor II at the Western Norway University of Applied Sciences. He has worked with issues related to energy, transport and sustainable development since 1988. In this work, Holden combines technological-oriented environmental studies, sociological and socio-psychological behavioural studies, and physical planning studies. Since 2008 he has also worked with projects related to renewable energy projects' impacts on local economies, local societies, and local environments in pursuing a sustainable energy policy. He is author of *The Imperatives of Sustainable Development* (2017. Abingdon: Routledge) and *Achieving Sustainable Mobility* (2007. Farnham: Ashgate).

Geoffrey Gilpin is an associate professor in the Renewable Energy Program at the Western Norway University of Applied Sciences. He holds a PhD (2016) Environmental Physics and Renewable Energy from the Department of Mathematical Sciences and Technology, at the Norwegian University of Life Sciences (NMBU). He worked as a researcher at NMBU (2006–2008), at the Western Norway Research Institute (2008–15), and in his current position works primarily in the application of industrial ecology methods to the fields of renewable energy and sustainability.

Background

Humans are headed into a mobility revolution, thanks to the emergence of self-driving vehicles. Tesla's "Autopilot" feature has been used by many consumers in freeway conditions, and testing of fully automated or "autonomous" vehicles (AVs) has become rather common in many settings, like the City of San Francisco, Phoenix metro area, and Detroit region. Technological improvements and investments by vehicle manufacturers and technology companies suggest that AVs will be publicly accessible in many locations within 10 years, although design, production, and licensing challenges remain.

AV technologies may radically change several aspects of personal trip making and freight mobility, including crash counts and congestion, energy use and emissions, and land use decisions. For certain impact areas, one may be confident that benefits will outweigh costs, such as in safety and vehicle efficiency per mile driven. In the case of other impact areas, it is not clear whether the automation of vehicles ultimately will be viewed as beneficial, since making "driving" easier adds demand to already congested roadways and can support further regional sprawl. Predicting AVs' direct and indirect effects is a daunting task, given the uncertainties inherent in AV technology development, public attitudes, policymaking, and safety standards. Nevertheless, it is valuable at this early stage to try understanding all potential implications in order to move toward more sustainable/less unsustainable travel choices and urban systems.

This paper provides an overview of such topics by surveying recent research results and publicly available reports. After a discussion of AV adoption forecasts, we examine travel choice, traffic and congestion impacts, shared vehicle systems, and shared rides. We conclude with a discussion on potential impacts for freight movement. Readers are referred to many references throughout these sections, including a section on "Further Reading" for more details.

AV Adoption

There has been much news hype regarding release of AVs to the public, driven in part by competition within the manufacturing space, for investment and returns. Machine learning algorithms have advanced quickly, while sensor prices have fallen, but "corner cases" in design remain daunting (unusual situations that could bring to wrong detection) and LiDAR remains expensive. Some of the most detailed work in household-fleet forecasting, recognizing the long lifetime (17 years on average) of existing household vehicles, includes that by [Bansal and Kockelman \(2017\)](#), who surveyed thousands of Americans regarding their vehicle holding choices and simulated, year by year, US household fleet evolution. Those predictions do not suggest 80% adoption until year 2050 or later, without public policy interventions (like AV-only requirements in sales and/or use at certain points in time). Using a bass diffusion model, with parameters based on the adoption of other technologies in the United States, [Lavasani et al. \(2016\)](#) suspect that technology cost will play little role. [Clements and Kockelman \(2017\)](#) estimate the value-of-time and crash-avoidance benefits to be so valuable to most travelers in developed countries (with high wages) that the choice may be easy (saving drivers effectively 100 + hours of time or almost \$2,000 in time-cost every year, with similar property and injury benefits), once vehicles become available in showrooms. But experience can be critical, and manufacturers do not want to release vehicles that are not yet ready for prime-time success. As to the potential initial customers of AVs, they will likely be young, more educated, and more frequent travelers ([Haboucha et al., 2017](#)). The major determinants behind their adoption are consumer perceptions of their improved usefulness and trustworthiness ([Choi and Ji, 2015](#).)

People's opinions can and do change, based on what they and their colleagues, friends, family members, and neighbors are experiencing (like being served by a shared AV (SAV) while on business travel). So preferences will evolve alongside AV cost

reductions and policymaking, presumably shifting those survey-data-based adoption curves to higher ownership and use rates. In addition, most or nearly all early AV releases may be to professional fleet managers (like existing car-rental companies and ride-hailing companies), who sign lengthy contracts agreeing to restricted use cases (like specific corridors and weather contexts, under specific lighting situations) and special maintenance provisions (like daily equipment reboots, algorithm checks, and sensor cleaning). So household AV adoption may not be nearly as important as SAV release and adoption, raising roadways' AV vehicle-miles traveled (VMT) quickly. Attitudinal and lifestyle factors, such as a person's tech-savviness and past use of ride-hailing services, together with safety concerns and expectations of driving automation, will play important roles in AV and SAV adoption (Bansal et al., 2016; Lavieri et al., 2017; Nazari et al., 2018). The extensive US survey work and household simulation over time suggest that one-third of US personal ground travel in year 2050 may be by SAVs (with about one-third of that in true ride-sharing—with a stranger) and that 60% or more of VMT should be in self-driving mode.

Travel Behavior Impacts

Vehicle automation is widely agreed to affect travelers' travel cost and experiences—both monetary and perceived. The fixed costs of owning an AV will be high (at least in the early, adoption phase) to accommodate expensive equipment, including computers and cameras, radar and presumably LiDAR, automated controls and wireless communications for safe, accurate, and rapid navigation. Initial prices are expected to be \$20,000 or more above base comparable vehicles (Fagnant and Kockelman 2018, Litman, 2019). Maintenance costs may rise as well, thanks to the added vehicle complexity, specialized sensor maintenance, and more expensive equipment replacement (Litman, 2019). On the other hand, AV operating costs should fall, thanks to sizable reductions in collision insurance costs (Bösch et al., 2018; Fagnant and Kockelman, 2015) and per-mile fuel savings of 5%–20%, depending on driving environment and user preferences, thanks to speed synchronization, inter-vehicle coordination, and eco driving (Lee and Kockelman 2019; Stephens et al., 2016). Parking search and use costs may also fall, as travelers rely on SAVs for many trips to high-parking-cost locations (like central business districts) and/or if AVs are permitted to park away from where they drop off their owners/users (Litman, 2019) and/or at least better anticipate available spaces (Shoup, 2006).

There is not yet strong agreement on the value of travel time (VOTT) effects of using AVs. Most experts expect significant VOTT reductions since AVs allow former drivers (though not former passengers, presumably) to suddenly engage in leisure and work activities (Auld et al., 2017; Bansal and Kockelman, 2017; van den Berg and Verhoef, 2016; Zhao and Kockelman, 2018) and to reduce driving stress (Singleton, 2019). Of course, being stuck in a vehicle is still limiting, so VOTTs are not expected to fall more, say, 50% for drivers (Cyganski et al., 2015; Lenz et al., 2016; Yap et al., 2016). Given the importance of VOTT assumptions in travel demand modeling and network performance predictions, further research involving revealed preference data (rather than stated preference surveys) is needed.

A key outcome of lower VOTTs is higher VMT. This addition to VMT comes alongside empty driving by SAVs, better “driving” access for those with disabilities (Harper et al., 2016) and lowered monetary costs of “driving” that translates in higher frequencies and longer distance traveled to the detriment of public transit and active modes competitiveness (Loeb and Kockelman, 2019; Simoni et al., 2019). All together, these behavioral changes portend a potentially dramatic rise in VMT demand and thus very serious congestion issues. Different simulation-based studies anticipate overall VMT increases between 10% and 50% from the adoption of (privately owned) AVs, depending on their cost and competition with other modes (Auld et al., 2017; Kim et al., 2015; Zhang et al., 2018). Significant increases are also evident in SAV-focused studies (Childress et al., 2015; Fagnant and Kockelman 2018; Liu et al., 2017; Loeb and Kockelman, 2019), due to about 5%–25% extra VMT from empty driving between passengers. Finally, AVs may dramatically affect long-distance travel choices (modes and destinations), by reducing air and rail travel by passengers and freight, while increasing highway travel between regions (Huang and Kockelman, 2018; Perrine et al., 2017).

In order to limit the externalities related to the increase of motorized trips, different travel demand management strategies could be adopted. Lamotte et al. (2017) propose a reservation-based strategy to manage automated vehicles' departures in Vickrey's bottleneck model. Simoni et al. (2019) assess alternative congestion pricing schemes to curb AV and SAV demand in alternative future scenarios. Tscharaktschiew and Evangelinos (2019) evaluate tolls to affect travelers' decision to switch between autonomous and manual driving and limit congestion. Conversely, Lee and Kockelman (2019) suggest that traffic flow benefits from AV adoption might obviate the need of congestion pricing schemes.

Traffic Impacts

Connected and automated driving systems (CADS) may increase traffic flow along lanes and through intersections and other points of conflicts by improving reaction maneuvers and intervehicle coordination decisions, reducing headways and crashes, and facilitating merging and mini-platoons. Benefits over time ultimately depend on manufacturers' design decisions, government regulations, and consumer adoption rates.

Thanks to having information on more vehicles around them, along with shorter reaction times, highly automated vehicles can reduce headways and increase road capacity (Hoogendoorn et al., 2014; Tientrakool et al., 2011; van Arem et al., 2006). For example, Shladover et al.'s (2012) simulations suggest basic-freeway link capacity increases up to 80%, simply thanks to full adoption and application of cooperative adaptive cruise control (CACC). Most existing studies anticipate considerable flow improvements only at

high adoption rates (e.g., above 50%), but [Jerath and Brennan \(2012\)](#) and [Kesting et al. \(2008\)](#) anticipate benefits at lower rates (e.g., above 30%). [Talebpoor and Mahmassani \(2016\)](#) by means of microsimulation identify automation as the main factor behind the capacity improvement (thanks to a significant increase of traffic stability) especially in comparison to communication technologies implemented alone. However, the highest benefits will be mostly likely achieved by the possibility of quickly sharing traffic information among vehicles, processing it by means of advanced algorithms, and identifying efficient solutions without involving humans.

Some recent theoretical traffic-flow work emphasizes general formulations for feasible lane policies ([Chen et al., 2016](#)) and adaptations of existing models ([Levin and Boyles, 2016](#)) to try and reproduce mixed-flow behaviors involving both, conventionally driven and fully automated vehicles. By investigating the influence of different factors (e.g., minimum inter-vehicle spacing, headway options, and market penetration, researchers like [Bujanovic and Lochrane \(2018\)](#) developed analytical models for predicting platoons' traffic effects based on platoon lengths and CADS penetration rates.

Other studies have focused on achieving better road network use via innovative control strategies using advanced automation and communication technologies. For example, [Dresner and Stone \(2008\)](#) proposed, and then microsimulated autonomous intersection management, where vehicles approaching an intersection can coordinate arrivals and movements via reservation, greatly reducing travel delays. [Sharon et al. \(2017\)](#) developed link-based "micro-tolls" across a downtown network that dynamically vary to reflect and thus lower congestion costs from AVs' routing choices. Several (CACC)-based strategies have been developed to stabilize traffic flows and thereby help avoid triggering certain types of congestion ([Milanés and Shladover, 2014](#); [Naus et al., 2010](#); [Wang et al., 2014](#)). The estimated capacity gain from CACC-equipped vehicles can almost correspond to 90% of the original throughput for low headways (e.g., below 1 s) and high penetration rates (above 90%). [Zhou et al. \(2017\)](#) proposed an AV-based strategy to maximize highway on-ramps' efficiency by smoothening traffic oscillations with halved speed dispersion rates for 25% AV penetration rates. [Stern et al. \(2018\)](#) show how a single AV can be effectively used to dampen stop-and-go waves (with 10%–15% throughput increases for a single AV controlling the flow of 20 "traditional" vehicles). [Wu et al. \(2018\)](#) obtained similar results using artificial intelligence-based control techniques for AV flows. It is worth mentioning that in these studies, only vehicular flows are investigated and conflicts with other modes such as pedestrians and cyclists are not considered.

Finally, CADS are expected to significantly reduce crashes rates ([Li and Kockelman, 2018](#)), since over 90% of public-roadway crashes involve human error ([NHTSA, 2008](#)). Since such crashes currently account for about 25% of roadway delay costs in the United States and presumably elsewhere ([Systematics, 2005](#)), CADS may reduce congestion costs by that much in the long run (assuming very high market penetration rates, which may come with regulations, much like seat belts and electronic stability control requirements on all new vehicles being sold in most developed countries). It should also be noted that reduction in nonrecurring congestion from crashes and from reduced congestion overall should improve reliability of the entire transportation system (by reducing uncertainty or variability in door-to-door travel times). This does require that AV technologies plus variable road pricing strategies, for example, are able to avoid the added congestion and potential gridlock that many expect from having too many AVs and other vehicles on the road). Moreover, improved safety and congestion delay reductions often involve a trade-off: in order to reduce crash likelihood, larger spacings between vehicles and lower speeds are often desired. Finally, long-term testing and programming will still be needed before this technology can guarantee zero (or close) risk of failure.

Shared Mobility: SAVs + DRS

High initial costs for vehicle automation, special maintenance needs, and use restrictions on early AVs will favor deployment of heavily used shared fleets of AVs or "SAVs". Since automation can significantly reduce operating costs for taxi and ride-hailing fleet owners or managers, transportation network companies (like Lyft, Uber, and Didi) are running AV tests ([Hawkings, 2017](#); [Kang, 2016](#)), investing considerable resources ([Buhr, 2017](#)) and developing strategic collaborations with automakers and governments ([Russell, 2017](#)) for future, large-scale SAV deployments. Automakers like Ford, GM, Fiat Chrysler, BMW, Daimler and Volvo are also considering the possibility of serving as SAV providers ([Stocker and Shaheen, 2017](#)). Even cities and local transportation authorities are considering SAVs as potential development for the future mobility services. For example, in 2016, Switzerland's largest bus company ([PostBus](#)) launched an AV shuttle service trial in the city of Sion to serve less accessible areas ([Lavars, 2016](#)). That same year, a local transit operator tested a similar service in Lyon, France ([Pultarova, 2016](#)). Since then, several cities worldwide have been launching similar pilot tests (e.g., Paris, Helsinki, and London in Europe, Ann Arbor and Las Vegas in the United States) in order to provide innovative "first-/last-mile" solutions (linking local vehicles with longer-distance, existing, fixed-rail investments, for example). Waymo, a Google-initiated program of SAVs, has been serving households around the Phoenix, Arizona region as well, using plug-in hybrid-electric minivans ([DeBord, 2018](#)).

From a sustainability perspective, self-driving, on-demand mobility can offer an attractive alternative to privately owned and, often, less fuel-efficient vehicles while ideally enabling efficient integration with existing transit system investments. Nevertheless, SAVs also often act in direct competition to existing public transport services, and can generate new VMT. In order to steer the development of SAV services in less unsustainable directions, it is important to better understand SAVs users' perceptions, along with likely operations, performance metrics, passenger-mile costs, and other SAV-fleet implications for mobility and the natural environment.

A few studies have explicitly explored SAV use tendencies, using stated preference surveys. [Bansal et al.'s \(2016\)](#) survey found that Austin, Texas respondents more inclined to state a willingness to use SAVs are males, full-time workers, tech-savvy individuals, and

those living in densely populated urban areas. Similarly, [Krueger et al. \(2016\)](#) identified relatively young males as the most interested demographic for use of SAVs via a survey across several major Australian cities. Meaningfully, a distinction between car drivers and car passengers emerged from this survey, with the latter more inclined to make use of SAVs with dynamic ride-sharing (DRS). Using paired comparisons of current and future travel modes in Germany, [Pakusch et al. \(2018\)](#) anticipated a growth of car sharing thanks to automation, and mainly at the expense of public transit. Although such studies can provide useful indications of trends and key factors at play in SAV adoption, reliance on stated preferences is always tricky. Other studies use existing parameters and estimates of VOTT changes to anticipate adoption rates largely via existing parameters and mode-cost estimates in transport planning models ([Davidson and Spinoulas, 2015](#); [Huang and Kockelman, 2019](#); [Lavieri et al., 2017](#); [Zhao and Kockelman, 2018](#)).

Fleet performance metrics are also crucial in anticipating SAV competitiveness and sustainability. Using simulation of vehicles and travelers, [Fagnant and Kockelman \(2015\)](#) demonstrated how SAVs may be able to replace up to 10 conventional vehicles in a small region or town while reducing carbon monoxide and various other emissions, at the expense of a 10%–20% increase in VMT. [Chen et al. \(2016\)](#) then explored the influence of different SAV-use pricing strategies with a fleet of range-constrained all-electric SAVs and highlighted trade-offs between fleet performance (including response times and empty VMT), fares, and overall demand for SAV services. In the case of all-electric SAVs, charging infrastructure investments and battery size/vehicle range can be crucial to the fleet's competitive performance ([Chen et al., 2016](#); [Loeb et al., 2018](#)). Furthermore, sophisticated customer assignment strategies (involving reassignment of travel requests among different vehicles) can be developed to improve fleet performance by lowering response times during the most congested hours ([Hyland and Mahmassani, 2018](#)).

Of course, dynamic/real-time matching of overlapping rides for distinct travelers via DRS should also reduce SAVs' congestion impacts and environmental footprint. A few studies, mainly based on simulation, have explicitly explored the issue of DRS for SAVs and examined the propensity to share rides based on fares and levels-of-service ([Fagnant and Kockelman 2018](#); [Farhan and Chen, 2018](#); [Loeb and Kockelman, 2019](#)). Recently, [Gurumurthy et al. \(2019\)](#) found that pricing strategies reflecting overall levels of congestion and fleet usage can be particularly useful in incentivizing users to adopt DRS and thereby reduce SAVs' VMT.

Freight Transportation

Automation will affect freight transport via the use of platooned trucks relying on CACC technologies, self-driving trucks, drone deliveries, and ground-based robots. AV research in freight transport has focused on long-distance trucking applications and drone-based delivery systems.

Assisted highway trucking may be one of the first AV applications in public use, thanks to high trucking costs (for labor and vehicles) and long-distance use, making the economic case for AV investment clear and rather immediate. Using a random-utility-based multi-regional input-output mode of production and trade across the United States, [Huang and Kockelman \(2019\)](#) estimate a long-term shift away from conventional trucks and railroad to automated heavy trucks for routes over 500 miles. Smart, safe, truck-driving, and vehicle-following algorithms can improve safety, give operators needed rest for longer drives, and decrease fuel consumption by about 10%, when platooned ([Alam et al., 2015](#); [Bergenheim et al., 2012](#); [Tsugawa et al., 2011](#)). Operators may take control for the shortest and most complex sections of long journeys while dealing with other tasks and supervising the cruise during the long legs of the trip. Although truck platooning has been successfully tested worldwide in the last few years ([Tsugawa et al., 2016](#)) several safety issues (e.g., V2V communication failures, hijacking, infrastructure constraints) and regulations (e.g., platoon size limits, road prohibitions, liability rules) will need to be addressed before implementation ([Janssen et al., 2015](#)).

Smaller, autonomous, or semiautonomous ground vans and single-unit trucks may also be employed for delivery, with a person on board to perform loading/unloading tasks and/or with different compartments that can be unlocked by customers at destinations ([DHL, 2014](#)). Drones or Unmanned Aerial Vehicles (UAVs) may soon improve supply chains and freight operations by delivering very small (weighting less than 3 kilograms) packages over the "last mile" of urban trips and/or by performing deliveries in less accessible areas. UAV use offers several advantages over conventional vehicles. For example, drones can typically perform quicker deliveries than trucks since they are not as constrained by street networks (although they might be mandated to fly over public right of ways in cities) and hindered by congestion. They also can more easily deliver lightweight packages in rural areas with low demand and in difficult terrains. Various supply chain businesses (like Amazon, DHL, and Google) have been testing drone-based solutions in an effort to reduce last-leg distribution costs ([Hern, 2014](#)). In 2019 UPS started the first commercial drone-delivery service in order to deliver medical supplies in North Carolina ([Stradling, 2019](#)). Several recent studies have explored the profitability of drones and their integration in current delivery systems using optimization and business approaches ([Otto et al. \(2018\)](#) for a comprehensive review). Depending on the speed, flight range, carrying capacity, and deployment strategy drones can yield up to 30% savings (over the traditional TSP) in total delivery time ([Agatz et al., 2018](#); [Murray and Chu, 2015](#)). However, drones will probably be employed for only a small share of total delivery volumes because of fly-height and battery-range restrictions. Public safety concerns can also slow their adoption.

Another automotive innovation with potential applications in the area of last-mile freight distribution is delivery robots. Several companies are exploring the possibility of delivering groceries and parcels via robots operating on sidewalks (Starship, Dispatch, Marble) and roads (Nuro). Similarly to drones, robots could be employed in combination with larger delivery trucks that cannot so easily penetrate neighborhoods or park in front of delivery addresses. Before large-scale implementation, however, issues related to their operations in crowded areas and regulations will need to be addressed ([Hoffmann and Prause, 2018](#)).

Conclusion

AVs are expected to transform the passenger and freight mobility landscapes in several ways. This chapter discusses their expected impacts on travel choices, traffic flows, shared mobility, and freight distribution, by reviewing various research findings. Several decades may pass before AVs' large-scale impacts become visible in most locations, due the technological challenges, costs, and other complex issues that surround AV use—including public perceptions, demonstrated safety statistics, liability (for manufacturers as well as policy makers), market trends, and specific deployment decisions and settings. Nevertheless, it is important to gain a better understanding of AVs' many potential effects at this early stage, in order to foster more sustainable travel choices and smarter transport-system investments.

While autonomous and connected driving has great potential to ultimately improve traffic efficiency, its extent will strongly depend on demand decisions, public policy, and user trust, in addition to technical challenges from algorithm and sensor development. As discussed here, travel costs for persons and freight are expected to fall thanks to once-drivers being able to perform other activities en route and travel longer distances without driver fatigue and sleep requirements. One downside of lower VOTTs, however, is a rise in trip making, motorized vehicle use, travel distances, and suddenly empty-vehicle travel. If empty VMT is not limited by law or pricing policies and local-intersection operational overhauls, congestion can become much worse in urban areas. Stated preference surveys and extensions of existing travel models offer meaningful indications of potential vehicle-choice, travel-choice, and network-condition changes, but additional research based on real observations will be needed in the future to better anticipate long-term shifts while developing more appropriate policies.

While added VMT may swamp any traffic benefits from AVs and SAVs, in the near term, highway and major arterial's streets' traffic performance may eventually benefit from the possibility of shorter headways and improved coordination at intersections. Within this context, advanced cellular and radio-based communication technologies will presumably play a key role in enabling effective coordination among vehicles and hopefully with pedestrians and cyclists. Moreover, shared mobility options may greatly facilitate inter-modal trips, higher-occupancy (shared-ride) vehicle use, and a regular reliance on battery-only vehicles without range anxiety for users. Of course, automation via drones and robots may also considerably change freight-delivery landscapes, in terms of last-mile distribution.

Introduction

The tourism industry, unlike other economic sectors, have proved to be particularly resilient to the various economic crises that have marked the last decades. Up to the rising of the COVID-19 pandemic in 2020, the sector, on a global scale, did not seem to have suffered drastic drops in flows, and showed trends of constant growth, also at an international level (UNWTO, 2018a, 2018b). It is questionable how long the effects of COVID-19 will characterize tourism. However, the upward long-term trend suggests the need and the opportunity to investigate the different elements of the phenomenon, focusing here, primarily, on the transport sector and its linkages with tourism.

This chapter is structured in two sections. The first one discusses the evolution of tourism and the consequent developments in the transport sector while the second one explores the complex relationships between transport and tourism. Some conclusions follow, mainly dealing with sustainability and methodological issues.

Historical Evolution of Tourism and Transport Modes

Transport toward a specific place has often been a crucial element of the accessibility of a tourist destination. Within this context, the historical evolution in the transport sector, especially in terms of innovation and technological development, by increasing the modal choice set, on one side, and by reducing costs (in terms of both time and tickets) and risks, on the other, has also scaled up the geographical tourism expansion, making it more and more a globalized phenomenon, affordable to ever largest shares of the population (Sorupia, 2005).

In this section, some brief notes (For a more in-depth and detailed historical description of the transport innovations that enhanced tourism improvement, see, for example, Gierczak, 2011) on tourism history will be the base to assess the mutual causality between transport and tourism.

The first tourists ever were travelers, prompted by curiosity toward unknown places, or actually discovering new trade routes, or driven by religious matters in pilgrimage; the transport modes at their disposal were mainly animals, like horses, provided that roads were built, for medium-long haul land traveling, or sailing ships, for maritime journeys, or feet, for short or spiritual trips.

Apart from commercial or religious matters, in the Grand Tour era (XVII-XIX century) people traveled throughout European cities in order to increase their culture and knowledge; due to the long time spent on traveling (more than a year), carriages for luggage and riches were necessary (Towner, 1985, 2002).

After the industrial revolution (second half of XVIII century) journeys became shorter, and transport sector worked hard to improve the quality of services and increase the speed of transport modes in order to cover space quickly: new roads, railroads and channels were built, while trains, stagecoaches and sailing ships kept on increasing the travel comfort.

Specifically, in the XIX century, the widespread use of the steam engine, invented by Watt in 1769, made rail and steamships very popular and cheap (Gierczak, 2011), while the invention of the gasoline engine and the consequent car diffusion in XX century has pushed motorized and flexible (door2door) tourism (Gierczak, 2011); air transport, operated by both scheduled and chartered airlines, also let tourists cover larger distances, making remote destinations more accessible.

Moreover, in more recent times (XXI century), with the introduction of low cost carriers, first reaching sunny coastal destinations, a simpler and more affordable air transport has definitely allowed many places to become a tourist destination. Furthermore, high-

speed rail (HSR) has come against air transport for medium-haul trips, due to the increased waiting times and inspections suffered by air travel, but also to the ever improved travel comfort in commercial rail journeys, while maritime trips have become more and more interesting as tourism itself (cruises) as much as a proper transport mode for getting from a place to another (hovercrafts for islands more than transatlantic lines); indeed, in this case, it is tourism that has pushed innovation into transport. Another example is the “roTEL”, a bus equipped for making travelers sleep onboard.

At the same time, the widespread concern for the environment and health has made active travel in tourism very popular, with many tourists choosing nonmotorized transport modes, such as walking (Hall et al., 2017) and cycling (den Hoed, 2019) not only at but also toward destination.

Finally, in the next future, space tourism could arise, given the right development of both transport vehicles and proper infrastructures.

Last but not least, the sudden growth of excursionists’ demand, together with the increased interest in transport within destination, call attention to local public transport modes, such as urban light rail, metro, bus and their infrastructure and services.

Interestingly, it must be noticed that nowadays tourists, traveling for both leisure or business, can choose among a large set of modes of transport (water, land, including rail and rail, or air), depending on their needs but also following their attitudes. Indeed, transport toward a destination or within destinations may also become an opportunity for “experiencing” the travel itself (e.g., sailing cruises), as well as for working (meeting area on the trains or planes) or enjoying a movie (boat cinema or devices at seat on HSR).

Transport and Tourism

It is widely acknowledged that transport and tourism are strictly interconnected (see, for example, Maltese, 2018; Zamparini and Maltese, 2021). Transport can normally be considered as one of the various complementary goods and services that characterize the tourism experience. There is clear evidence of a strong mutual causality. However, it is difficult to discriminate between tourists and resident users of the transport system. Therefore, the link between transport and tourism is very complex to analyze (Page and Ge, 2009). Consequently, most of the studies dealing with this connection end up privileging one of the two perspectives (tourism or transport) (Palhares, 2003). On the contrary, Page (2005) suggests that scholars should consider three main aspects of this link:

- the trip itself can become a tourism experience (transport as tourism);
- transport clearly encourages and facilitates tourism (transport for tourism);
- tourism promotes the development of the transport sector (tourism for transport);

In the following sections each of these issues will be analyzed and discussed.

Transport as Tourism

The first dimension that can be considered in the relationship between tourism and transport concerns the possibility that the trip is not functional to reach the tourist destination; it rather becomes a tourist experience itself.

In this case, the transport demand ceases to be a derived demand and provides tourists with the possibility of covering various ranges of distances. Long-distance trips are normally related to cruise ships (which have a diversified supply for all market segments) or to train journeys (e.g. the Indian Pacific line between Perth and Sidney in Australia or the famous Transiberian railway between Moscow and Vladivostok). Medium-haul trips are generally performed in camper vans, on trains, or on sailing boats. Short trips may also involve hikers or excursionists—for example on tourist buses, river boats, mountain trains or panoramic cable car or ropeway systems.

This category also includes some experiences on particular aircrafts (e.g., balloons, gliders or two-seater) and cycle tourism, as bikers or passengers, while in the last few years, space aircraft expensive “tours” have also been organized.

Moreover, the last decades have witnessed the diffusion of active travel and in particular of “walking” tourism. The latter can represent the individual tourist experience *per se*, in the medium-long distance, in the case of pilgrimage “walking”, or at the urban scale, to best “enjoy” the tourist destination. In this case, it is important that the considered town or neighborhood has a good “walkability” score, that can be measured by taking into account several variables such as: road safety, landscape aesthetics, the possibility of finding refreshment points and shelter (from the sun as rain), information poles (Le Pira et al., 2021).

Transport for Tourism

Transport is definitely a key component of the tourism product basket (Speakman, 2005), together with catering, accommodation, activities (such as visits to parks and museums, festivals, seminars and sport events) and shopping. Actually, the very definition of “tourism” (“Travelling to and staying in places outside one’s own usual environment for not more than one consecutive year for leisure and not less than 24 hours, business and other purposes” (WTO, 1995)), requires leisure or work

activities to be carried out in a place other than that of residence. Consequently, the need to go “elsewhere” (i.e., to cover the distance between the place of origin and the tourism destination) can only be satisfied by the use of any possible transport means, be it public or private.

Moreover, it could be worthwhile to distinguish between three different types of transport services that can be used by tourists, as they deal not only with different mobility patterns and different transport modes, but also with different aspects of the tourism experience.

Specifically, a tourist can make use of:

- Transport from the origin (e.g., place of residence) to the tourist destination and back;
- Transport within the tourist destination;
- Transport between multiple tourist destinations (during the same trip).

In the first case, which has attracted most of the literature about transport for tourism both at the domestic and at the international or intercontinental scale, accessibility to the tourist destination is the main theme of analysis. It heavily depends on a series of factors that include infrastructures, services (both unimodal and multimodal), a good degree of information and affordable tariffs (Van Wee et al., 2013). It has emerged that infrastructures and services play a momentous role to reach destinations that are particularly isolated or in any case distant from urban communities. In this context, low cost airlines have been able to expand their networks by including point to point connections to the most sought after tourist destinations.

More broadly speaking, the development of mass tourism has been determined by the conjoint effects of the evolution in the transport sector (that has reduced distances, times and costs, and has increased efficiency, travel comfort and service capacity) and of some socio-economic and regulatory phenomena (such as an increased leisure time availability and higher income levels, on one side, and the liberalization of passenger movement, on the other). This evolution has also attained the international scale and it has affected and has been affecting all the different modes of transport (Culpan, 1987; Duval, 2007).

Moving to the second point, when tourists choose a unique destination for their journey, it is important to consider transport within tourist destinations, given that it becomes a part of the tourism product offered by such destinations (Masiero & Zoltan, 2013; Prideaux, 2000). In these instances, that are mainly related to the urban scale, the local public transport (LPT from now on) plays a crucial role (Le-Klähn and Hall, 2015). It deals with several interesting aspects for tourism, such as: (1) the diffusion of the service that may allow to reach all the amenities that are present in the tourist destination; (2) the management of feeder services to and from the major transport hubs (airports, railway and maritime stations, etc.) in order to efficiently connect local transport with the national and international ones; (3) the proposal of specific offers or packages for tourists and the provision of tariff integration, possibly with some of the tourist activities that it is possible to perform at the tourist destination; (4) the management of the communication and information services, which may allow to digitally display maps, and pedestrian and cycle paths connected and adjacent to the LPT network. In the case in which the destination has a relevant share of foreign tourist demand, it is necessary to provide information in several different languages. A recent trend has been constituted by the substitution of LPT by active travel options (walking or cycling). This has been due to two main factors: (1) normally, the distances to be covered are relatively short and (2) the scarce attractiveness of the LPT, due to possible overcrowding or lower service regularity, as during and in the aftermath of the COVID-19 pandemic.

Finally, as concerns the third point, it may be taken into account that tourists normally want to make excursions to places that are in proximity to their main destination (Plog, 1974). In this case, agreements among several local administrations are necessary in order to improve the efficiency and effectiveness of interurban transport services (bus and railways, for the most, but also maritime routes) running from/connecting one location to another, to finance the upgrade of transport infrastructures, and to strengthen the degree of connectivity among the different locations especially in terms of joint planning, marketing, information and communication about tariffs, timetables and mobility options.

Tourism for Transport

If the contribution of transport to tourism is clear, the causal link between tourism and transport must certainly be better investigated. Indeed, the need to improve and specialize the transport service in order to cater for tourists' needs has led to numerous innovations and improvements in the transport sector, with many positive externalities for residents and city users (as commuters and elderly people). For example, new charter services have been set up based on the specific tourists demand, new routes have been induced by the development of a specific tourist destination, some lines and routes have been strengthened, through shuttle services and more generally by feeders that serve fundamental infrastructures (also) for tourism induced demand.

In some cases, infrastructures built from scratch or expanded compared to the existing ones and services that guarantee multi-modality are generated from the need to meet the tourists' demand. It then emerges that they have a momentous impact on the territorial and economic development (in terms of employment and of gross domestic product) of the region that encompasses the tourist destinations where these investments have been deployed. Moreover, some intangible aspects can also be induced by the tourism industry to the transport one, such as new marketing strategies, especially in terms of communication and digitization that

simplify the acquisition of information and the possibility of remote booking. Finally, as regards management, new services can be developed, such as offers based on demand segmentation and new tariff integration systems.

Conclusions

This chapter investigated the historical evolution of tourism and transport modes and the relationships between tourism and transport. The analytical framework for scrutinizing the mutual causality between transport and tourism has identified three different aspects: transport (toward or within destinations) for tourism, tourism for transport and tourism as transport, that can also occur simultaneously, depending on the considered transport mode.

Within this context, it can be concluded that the distinctions among transport modes and among the causality direction between transport and tourism are crucial for two main reasons.

The first one is methodological and concerns the (new) possibility to discriminate tourists from residents and city users. For example, transport toward destination, especially using those modes who need a personal identification of the travelers (airlines or HSR), is easier than walking within destination. Moreover, big data and technological devices (such a smartphone) could help in data collection for researchers (De Cantis et al., 2016; Dickinson et al., 2018; Lau and McKercher, 2006; Orellana et al., 2012; Xu et al., 2019; Zheng et al., 2017).

The second one regards the unavoidable sustainability issue concerning tourism transport (Hopkins, 2020). Taking into account that the transport mode towards the destination—and the motivations for choosing it—mostly affects the transport mode chosen at destination (Cohen and Kantenbacher, 2019; Gössling et al., 2019; Hergesell and Dickinger, 2013), it is firstly worthwhile noticing that an increased accessibility to some remote and isolated places can be harmful in terms of the derived negative externalities that may lead to long term problems for the destination region. Furthermore, also an over-crowded public vehicle (bus or local train) can be a negative externality for residents to minimize. Lastly, and more broadly speaking, it has been proved that environmental degradation reduces the destination attractiveness (Chen et al., 2017) and that transport is responsible for most of the negative externalities coming from tourism (Gössling, 2002). As a consequence, the concept of “sustainable tourism” should be enhanced (Becken, 2005; Boluk et al., 2017; Panzer-Krause, 2019; Peeters et al., 2019), making tourists aware of their impact even in terms of transport modal choice both toward and within destination(s) (Buijendijk et al., 2018; Maltese and Zamparini, 2021; McLennan et al., 2014), together with a suitable offer of public services and active travel infrastructures, adequately communicated, thus stimulating a more sustainable mobility (Banister, 2008; Barr and Prillwitz, 2012; Barr et al., 2010; Hall, 1999; Høyer, 2000; Prillwitz and Barr, 2011).

Biography

Ila Maltese holds a PhD in Urban Policies and Projects and is currently senior researcher at TRELab (Transport Research Lab) at the University of RomaTre in Rome. She also teaches Economics at the Faculties of “Political, Economic and Social Sciences” and “Humanities” at the University of Milan and at the Faculty of “Management and Production Engineering” at the Polytechnic of Milan. Her primary research interests include sustainable mobility at urban scale, both for passengers—tourists and residents—and freight, and smart city dimensions and drivers.

Luca Zamparini is an associate professor of Economics and currently chairing the courses of Economics and of Tourism Economics at the University of Salento (Italy). He is a coordinator of the cluster on Leisure, Recreation and Tourism for NECTAR (Network on European Communications and Transport Activity Research). His main fields of expertise are transport and tourism economics with an emphasis on the qualitative attributes of transport, on transport security, and on the relationships between transport and tourism development. He has edited various volumes, three special issues and has published many articles and chapters for international journals and books.

The Concept of Accessibility

Accessibility is a, if not: the, core concept in transport geography and transport planning. The transport system mainly aims to provide access to destinations of locations where people want to carry out activities such as living, working, education, shopping, recreating, and visiting other people. In case of goods, transport accessibility aims to allow companies to transport goods in different stages of production (from raw materials), via several intermediate stages to final (consumer) products, and (lastly waste materials) between locations (Geurs and van Wee, 2004). Briefly summarizing, it expresses the potential for interaction (Hansen, 1959; El-Geneidy and Levinson, 2011). Consequently, the main benefits of improvements in the transport system follow from providing access to destinations. Therefore, accessibility plays a dominant role in about all transport policy documents. But what is accessibility, how can it be defined, and which components influence final levels of accessibility? What is the state of knowledge, and which open challenges remain? This paper aims to answer these questions.

A main message is that multiple categories of indicators measuring accessibility exist, and that the choice between all those options depends on the purpose and context of the study. In addition, many research challenges could be a source of inspiration for researchers.

Definition and Components

The most downloaded paper in the *Journal of Transport Geography* is the paper on accessibility written by Geurs and van Wee (2004, p. 128) who define accessibility as “the extent to which land-use and transport systems enable (groups of) individuals to reach activities or destinations by means of a (combination of) transport mode(s).” Fig. 1 shows a conceptual model explaining which factors influence levels of accessibility.

In line with Fig. 1, accessibility levels depend on four components:

- The land-use component (visualized as activity locations): the land-use system describing what is located where (e.g., jobs, other people, shops, health services, schools, and recreation facilities).
- The transport component (travel resistance): characteristics of the transport system determining how much time, money, and effort it takes to travel between locations.
- The individual component (wants, needs, abilities, opportunities, etc.) expressing what people need or want, and are able to do.
- The temporal component, expressing that it matters at which time which (locations of) activities are available. For example, shops and kindergartens have specific opening times.

The temporal component is not explicitly included in Fig. 1, but applies to all the other three components: people might have time restrictions, and activities transport services might be available during a selection of hours.

Fig. 1 shows that accessibility levels depend on the locations of activities, travel resistance, expressed in terms of time, costs, and effort, and the wants and needs of people. And those factors influence each other. As recognized by the so-called land-use transport interaction (models), land use influences the transport system and vice versa. For example, if residential areas are built adjacent to a railway line, a new station may be built along that line. And vice versa: locations near stations or motorway entrances and exits are relatively attractive for urbanization. The interactions between land use and transport also play a role at the level of individuals and households. For example, if new infrastructure is build, it reduces transport resistance, and that reduced resistance can make people change their residential location or destination choice. Characteristics of the transport system might influence people's wants and needs, for example, preferences to own vehicles, and the wants and needs of people might influence their residential location, and vice versa. Opening hours of locations that attract many people might influence timetables of a public transport system, and vice versa.

Almost all accessibility measures make use of one or multiple of the four components. Depending on the selection of components, these measures can be clustered in families of measures (Geurs and van Wee, 2004):

- Infrastructure-based measures, focusing on the level of service of the transport system. Examples are travel times to destinations, congestion levels on roads, and the number of stations accessible within a time or distance threshold (transport component).
- Location-based measures (also called place-based measures), focusing on access to spatially distributed activities. Examples are contour measures such as the number of jobs accessible from residential locations within a certain time threshold value. More advanced examples correct for distance or time using decay functions expressing that locations further away are valued less (transport and land-use component).
- Person-based measures, focusing on the individual level, such as the activities available for a person within time or other constraints. These measures originate from time, or time-space geography (transport, land use, individual, and temporal component) (Kwan, 1998; Neutens, 2010).
- Utility-based measures, expressing the utility that people address to the options of having access to spatially distributed activities, the so-called logsum being an important example. The logsum is the log of the denominator of a so-called logit model. This denominator includes the choice options available (transport, land use, and individual component; temporal component sometimes via time of day, but only partly).

The use of one or multiple accessibility indicators should primarily be based on the aim of the research and the options available. More specifically for a specific purpose the choice can be based on next criteria:

- The quality of the theoretical underpinnings

Figure 1 A conceptual model for accessibility, activity locations, and travel behavior. Source: van Wee and Geurs (2016).

- The ease of operationalizing the indicators (availability of data, models, software, etc.)
- The ease of interpreting the indicators and communication results to clients of accessibility research
- The ease of including the indicators in evaluation frameworks like cost–benefit analyses (CBA) or multi-criteria analyses (MCA)

A dilemma exists because generally speaking easy to calculate and next communicate indicators (such as the number of jobs accessible within 45 minutes, or average speeds on the road or rail system) is theoretically less sound and can hardly be included in evaluation frameworks. On the contrary, the utility-based measures generally have theoretically sound underpinnings, but are difficult to calculate, certainly if a logit models-based transport model is not available, and communicate to many clients of research such as policy-makers (Geurs and van Wee, 2004).

ICT and Accessibility

Most of the accessibility literature only considers physical access to destinations. But increasingly information and communication technologies (ICT) provide alternatives, examples being skypeing for personal communication, e-shopping, e-working, and e-learning. So, to fully understand accessibility, in the future researchers and policy-makers should take notice of the relationships between ICT and accessibility. These relationships are quite complex, as visualized by Fig. 2.

Some examples of interactions are: because of the option to e-shops shops might relocate. Or congestion levels decrease if more people can e-work and therefore avoid the rush hours. It can also influence the wants and needs of people: they might consider access to shops or jobs less important if ICT-based alternatives are available. And people might be more inclined to multitask thanks to ICT, performing ICT-based activities while traveling by train being an example, and the option to multitask while traveling might reduce the willingness of train travelers to pay for shorter travel times. Therefore, the valuation of characteristics of the transport system might also change as a consequence. ICT might also relief time constraints, such as due to limited opening hours of shops. Not only does ICT provide alternatives for physical activities, it also can generate activities. For example, people might have met electronically and after some contacts they decide to meet in person. And due to ICT people might reorganize their activities over time and space. Next, ICT can also influence travel mode, departure time, and route choice, for example, because of the availability of real-time travel information.

Challenges for Future Research

Transport Modes, Travel, and Activities-Related Challenges

van Wee (2016) suggests several challenges for future research. The first category of challenges is content related; in other words, they focus on transport modes and activities.

Figure 2 Relationships between ICT and accessibility components. Source: van Wee et al. (2013).

ICT

The importance of ICT for accessibility is explained earlier. ICT can influence accessibility in many complex ways, as illustrated in Fig. 2. The accessibility literature so far has not, in a mature way, discussed how to include these links between ICT and accessibility in accessibility research. Such research should also include the dynamics in ICT options being available. One can think of advanced options to combine modes via Mobility as Service (MAAS) (information, ticketing, etc.), car and bike sharing, e-learning and e-shopping options, etc.

In addition to including ICT in indicators for accessibility, this process will also generate new (big) data for accessibility analyses, via GPS-based data track and log systems, social media, and traffic flow-related data systems. A challenge is the assessment of the representativeness of these data because the use of related systems (e.g., social media) is not equally spread amongst the population. And early adopters of innovations might in some respects differ from the wider audience.

Short Distances and Slow Modes

The emphasis in the accessibility literature has largely been on longer distances and on car and public transport, often related to job accessibility. Active modes (walking and cycling) and nearby destinations have received much less attention, but can be very important for people, especially for having access to grocery shops, medical and other services, kindergartens, etc. Research in this area should include the specific context, for example, with respect to the quality of infrastructure for walking and cycling, and climate conditions.

Multiple Modes

People often combine modes to reach destinations, but the literature on multimodal accessibility is relatively underdeveloped. Furthermore, the fact that people can travel to destinations via multiple unimodal trips (e.g., either drive or cycle, or travel by public transport) is also often ignored in accessibility analyses. Additionally, for international trips people might positively value having available both aircraft and high-speed train options. The level of long-distance accessibility levels via these modes also depends on options to travel to and from airports and HSR station.

Robustness

Since the early 2000s academic literature has recognized the importance of related concepts like robustness, vulnerability, resilience, reliability, flexibility, and travel time variability. Using the term “robustness” as an umbrella term, it is important to recognize the different time scales at which robustness plays a role, ranging from short-term disruptions while traveling to several decades due to the impact of climate change on the transport system. And the relevance also differs strongly ranging from minor disruptions to disasters-related evacuations. A general challenge is to include robustness in accessibility indicators and next analyses.

Perception of Accessibility

Researchers generally calculate accessibility levels based on locations of opportunities, and characteristics of the transport system, and in some cases time constraint and personal characteristics (like car availability). But perceived accessibility, typically used when making choices, is seldom studied. Perceived accessibility can differ from calculated levels, for several reasons, the first example being that people might have misperceptions about the quality of nonused modes or opportunities. It can also be that they include additional characteristics of travel options, such as the attractiveness of the route or perceived social safety, or additional characteristics of opportunities, such as price and service levels of shops. The concept of perceived accessibility so far has not received a lot of attention, but for many people it could be more important than calculated levels of accessibility.

On a side note: in some literature perceived accessibility is sometime labeled as “subjective accessibility,” and calculated accessibility as “objective accessibility.” The terms “objective” and “subjective” are misused here, because measured accessibility does not perfectly reflect all characteristics of travel and opportunity characteristics, and subjective accessibility might include aspects that can objectively be assessed.

Air Transport

Overland transport (car, public transport, and, to a lesser extent, active modes) has dominated the accessibility literature. Long-distance transport, mainly air transport but also high-speed rail, has received less attention. But because of the rapid growth in long distance, transport accessibility by aircraft and high-speed rail is becoming increasingly important. In that area it is not only the direct and indirect (including stopovers) that matter, but also the frequencies, timetables, and prices. And it is important to include that frequencies are subject to diminishing returns: the higher the frequency, the lower the added value of a further increase in the frequency.

Goods Transport

Goods transport is an underexplored area in the accessibility research. It is way less studied in general, and also the importance of the concept, the decomposition between the accessibility components, and the choice of indicators are poorly understood, making it a challenging topic for research. Research in this realm should at least consider that goods do not “experience” travel, unlike people.

Transport Innovations

The impact of innovations in the transport system (and ICT—see earlier) is poorly understood. Examples of innovations in the transport system include autonomous vehicles, MaaS, e-bikes, electric vehicles, and improved information systems such as those forecasting travel times. Note that ICT also contributes to MaaS and forecasting travel times, and other ICT innovations can contribute to improved options to e-learning, e-shopping, and e-working.

Developing Countries

Most applications of accessibility literature focus on developed countries. Many challenges for accessibility analyses of developing countries exist especially due to the lack of available data. Maybe in the future this might change to some extent, because of the availability of big data for travel and activities of people. Another challenge could be that context matters. For example, the social status of modes can differ between countries, as well as preferences for activities (informal jobs, social ties, etc.) and social safety while traveling.

Evaluation-Related Challenges

The next category of challenges relates to the evaluation of accessibility levels.

The Integration of Accessibility in Wider Evaluations

Accessibility is not the only relevant topic for evaluations of (policies for) the transport and land-use system. An important question therefore is: how to include accessibility analyses in wider evaluation frameworks like CBA and MCA? CBA is the most common evaluation framework for at least transport infrastructure projects, but it is also often applied for other topics such as road pricing options. Because a CBA expresses anything that people value in monetary terms, accessibility indicators that express accessibility in monetary terms can relatively easily be included in CBAs. In all other cases, a major question is how to include accessibility analyses in CBAs.

In case of an MCA, results of accessibility can relatively easily be included. The main challenge is to come to adequate weight factors, relative to other important impacts of the transport system, like safety, several environmental impacts, investment, and maintenance costs.

The Logsum as an Accessibility Indicator

The logsum is an indicator that—under specific assumptions—can be used to assess the monetary value of accessibility levels. It is the log of the denominator of a discrete choice model, and that denominator includes travel options to opportunities.

But there are several challenges to further improve the logsum as an accessibility indicator. It ignores the fact that people value having multiple-choice options available, and—related—the love for variety in consumption. And it estimates the value of the decision, not necessarily the experienced utility. And the indicator is difficult to explain to nonexperts. Finally, the so-called IIA assumption of logit models can be violated due to autocorrelation, in case of destination choice.

Distribution Effects, Equity, and Social Exclusion

Accessibility indicators and accessibility studies generally ignore distribution effects and other equity-related issues (e.g., the fact that promises are made to a city or region), and levels of social exclusion. Since about 2010 ([Martens, 2017](#)), these topics have increasingly received attention of researchers, and consequently the inclusion of such topics in accessibility analyses will probably become more important in the future.

The challenge is not so much the development of indicators to study equity aspects of accessibility, because it can make use of indicators that are calculated anyway. And next these can be used to make explicit, for example, the distribution of accessibility levels over income groups or areas. A more daunting challenge is to include the indicators in broader evaluation frameworks, especially CBA. Another challenge is the underpinning of such indicators by ethical theories, although in recent years substantial progress has been made, dominant theories used being sufficientarianism, egalitarianism, and the capabilities approach. Another area for future research is the underpinning of quantitative yardsticks to label people of being socially excluded.

Option Value

People value available options, even if they do not use them. This is referred to in the (economic) literature as the option value ([Geurs et al., 2006](#)). For example, people might value of being able to travel by train, for the rare case of a roadblock, an event that might even never occur for them. The concept of the option value has seldom been included in the accessibility literature.

Freedom of Choice

People value being able to make choices, as expressed by the so-called concept of the “freedom of choice.” So far the accessibility literature has hardly included this concept. It is partly related to the so-called option value (see earlier) but that concept only relates to the availability of options, not to the freedom to choose between options.

Comparisons of Indicators for Real-World Cases

As explained earlier, many accessibility indicators exist, and choosing the “right” indicator for a specific study is not always easy because each indicator has its pros and cons. As explained earlier, there is a trade-off between the ease of communication and scientific quality. Comparing indicators for a specific application can be very relevant, first because it allows the researcher to find out how robust results are for indicator choices. Secondly, if complex indicators would lead to about the same conclusions as simple indicators, it could be an option to communicate the simple indicators to policy-makers and other clients of research, knowing that the results will be about the same if more difficult to interpret indicators would have been used.

The Wishes of the Client

Research studying what the clients of accessibility research need has hardly been done. In other words, we poorly understand the preferences of clients of accessibility analyses. Because a lot of accessibility analyses aims to support decision-making processes, it is an important avenue for future researchers to study those preference.

Concluding Remarks

Despite the fact that it is more than half a century ago that the seminal paper of Hansen about accessibility was published, the concept is still evolving, and there still are many definitions and indicators. In addition, several research challenges remain, not only because of weaknesses in current research, but also because society is changing in many ways, the impact of ICT being one important factor. This makes accessibility research an inspiring category of research, both for academics and for practice.

Biography

Bert van Wee is professor in Transport Policy at Delft University of Technology, the Netherlands, faculty Technology, Policy and Management. In addition, he is scientific director of TRAIL research school. His main interests are in long-term developments in transport, in particular in the areas of accessibility, land-use transport interaction, (evaluation of) large infrastructure projects, the environment, safety, policy analyses, and ethics.

Introduction: Modes as the Linchpin of the Global Economy

Transportation modes are the conveyances used to support the mobility of passengers and freight (Sultana and Weber, 2017). The substantial diversity, availability, and affordability of goods in the global economy much depend on the capacity to transport them. For instance, a mobile phone manufactured (assembled) in China embarks in a complex journey, involving a multitude of stages with transport modes such as trucks, containerships and trains, and with transport facilities such as ports, railyards, and distribution centers, to ensure that it reaches global markets. This does not even consider the staggering array of movements related to the components of this device. For passengers, increasing international interactions linked with social interactions, business transactions, tourism, sport events and migration has been an ongoing trend. The mobility of passengers and freight within the global economy must thus be supported by transportation modes, terminals, and infrastructures (Black, 2003).

This chapter is organized as follows: The first section provides an historical perspective behind the emergence of major transportation modes and their impacts on globalization. The second section underlines the benefits of intermodalism. The third section looks that two fundamental modes supporting international mobility, maritime, and air transport. The fourth section focuses about how logistics allows for the organization of modes supporting global supply chains.

The Emergence of a Global Transportation System

International transportation predates globalization since for as long that there has been trade, transportation modes have been its conveyances. One is the prerequisite for the other; they are both mutually interdependent. The history of transportation modes is a proxy of the history of globalization with the volume, capacity, speed, and efficiency of transport modes evolving (Bernstein, 2008). As economies and societies emerged, axis of trade and circulation came into existence. One of the first major “international” trade route was the Silk Road, its name taken from the prized Chinese textile that flowed from Asia to the Middle East and Europe. The Silk Road consisted of a succession of trails followed by caravans through Central Asia. Since the transport capacity was limited, taking place over long distance and often unsafe, luxury goods were the only commodities that could be traded. The Silk Road also helped the diffusion of ideas and religions (initially Buddhism and then Islam), enabling civilizations from Europe, the Middle East, and Asia to interact. The road endured from the 2nd century BC to the 15th century when more efficient maritime transportation helped its downfall. A rudimentary system of international trade was thus permitted.

The transport system of the Roman Empire put in place between the 3rd century BC and the 2nd century AD was a fundamental component of a Mediterranean system of trade with two interdependent transport systems; the road and short distance, coastal, maritime shipping. The Mediterranean Ocean provided a central role to support trade between the major cities of Empire, most of them being located along the coast (e.g., Rome, Constantinople, Alexandria, Cartage). These cities were serviced by a road network permitting trade within their respective hinterlands. For instance, the world’s first dual carriageway, Via Portuensis, was built to link Rome and the port of Ostia at the mouth of the Tiber River. At the peak of the Roman Empire around 200 CE, its road system covered about 80,000 kilometers, but once the empire collapsed in the 5th century, the road system fell into disrepair and became fragmented.

It is, however, with long distance maritime transportation that more globally oriented economic systems were permitted, with the creation of commercial empires. Initially, ships were propelled by rowers, and sails were added around 2,500 BC as a complementary form of propulsion. China was one of the first to establish an important fluvial transport network with several

artificial canals connected to form the Grand Canal. At its peak in the 15th century, the canal system totaled 2500 kilometers, with some parts still being used today. By Medieval times, an extensive maritime trade network, the highways of the time, centered along the navigable rivers, canals, and coastal waters of Europe was established. Shipping was extensive and sophisticated using the English Channel, the North Sea, the Baltic and the Mediterranean where the most important cities were coastal or inland ports. Still, transportation was mainly a short distance and very risky endeavor with long distance maritime routes mainly controlled by Arab merchants linking the Middle East, South Asia, and Southeast Asia.

By the 14th century galleys were finally replaced by full-fledged sailships (the caravel and then the galleon) that were faster and required smaller crews. In total, 1431 marked the beginning of the European expansion with the discovery by the Portuguese of the North Atlantic circular wind pattern, better known as the trade winds. A similar pattern was also found on the Indian and Pacific oceans with the monsoon winds (long discovered by the Arabs). The ensuing era of colonialism was mainly the era of the sailship, linking Europe with the rest of the world. Although shipping services were rather sporadic, large colonial empires such as those of the Spanish, British, French, and Dutch were the early expression of a global economy supported by the sailship. For instance, the Dutch East Asian Company, founded in 1602, can be considered as one of the first multinational corporations. By 1750, it employed around 25,000 people and did business in more than 10 countries, mainly from the Dutch colony of Indonesia.

The beginning of the 19th century saw the establishment of the first regular maritime routes linking port cities worldwide, especially over the North Atlantic between Europe and North America. Sailships became increasingly efficient, with some like the Clipper ships mainly designed for speed more than for cargo holding. These “express” cargo ships dominated long distance ocean trade until the late 1850s when they were gradually replaced by steamships. Another significant improvement resided in the elaboration of accurate navigation charts where prevailing winds and sea currents could be used to the advantage of navigation. The improvement of steam engine technology permitted longer and safer voyages. The first regular services for transatlantic passenger transport by steamships were inaugurated in 1838 and until the mid-20th century, Liners accounted for most of international passenger travel. In the 1840s, it took about 12 days for a Liner to cross the Atlantic, a figure that dropped to 4 days in the 1930s.

By the end of the 19th century additional improvements in engine propulsion technology and a gradual shift from coal to oil as a fuel increased the speed and the capacity of maritime transport. Energy consumption by maritime shipping was reduced, and coal refueling stages were bypassed. An equal size oil-powered ship could transport more freight than a coal-powered ship, reducing operation costs considerably and extending its range. Global maritime circulation was also dramatically improved when shortcuts such as the Suez (1869) and the Panama (1914) canals, were constructed. With the Suez Canal, the far reaches of Asia and Australia became more accessible, while the Panama Canal considerably reduced the time it took to link the Atlantic to the Pacific.

The capacity of maritime shipping also increased with the specialization of ships, which enabled to move low-cost bulk commodities such as minerals and grain over long distances. The size of oil tankers grew substantially, especially after World War II when global energy demands surged. Maritime routes were thus expanded to include tanker routes, notably from the Middle East, the dominant global producer of oil. To this day, energy trades are among the foremost forms of modal globalization as they concern large quantities of goods usually carried over long distances.

The airline industry has also played a significant role in supporting the emergence of a global economy. It began with air mail services since they initially proved to be more profitable than transporting passengers. 1919 marked the first commercial air transport service between England and France, but air transport suffered from limitations in terms of capacity and range. The late 1920s and 1930s saw the expansion of regional and national air transport services in Europe and the United States with successful propeller aircrafts such as the Douglas DC-3. The post-World War II period was, however, the turning point for air transportation as the range, capacity, and speed of aircrafts increased. A growing number of people were able to afford the speed and convenience of air transportation. In 1958, the first commercial jet plane, the Boeing 707, entered in service and revolutionized international movements of passengers, marking the end of liner ships, leaving the maritime passenger sector to the niche markets of cruises and ferries. The cruise ship became a new mode of globalization in the tourism industry, offering itineraries in a variety of regional markets. The availability of the Boeing 747 in the early 1970s truly made air transport a global industry. Still, passenger transportation is a marginal, albeit visible, component of globalization.

By the second half of the 20th century, many international transportation systems were in place, forming the basis of a global transport system and reinforced by a global telecommunication network. Fundamental changes were about to take place as the role of transportation evolved. From a situation where transportation was a simple infrastructure permitting and supporting trade and mobility, transportation became a factor shaping global production and markets. The fragmentation of the production and an international division of labor increased the quantity of freight in circulation. Containers have been particularly important in this regard. Introduced in the late 1950s, containers became the main agents of the modern international transport system.

Connecting Modes: Containerization and Intermodal Transportation

While modal transportation is the mean supporting global mobility, intermodalism allows for the connectivity within and between large systems of circulation (Rodrigue, 2017). The container epitomizes this connectivity in the freight sector as a load unit that can

be used by several transport modes. Maritime, railway, and road modes are all able to handle containers, increasing the flexibility of freight transport, mainly by reducing transshipment costs and delays. Containerization underlines a growing relationship between freight transportation modes and a standardization of loads. The container has a reference size of 20 feet long, 8 feet high, and 8 feet wide, corresponding to a 20-foot equivalent unit. The most common containers are 40 feet in length, permitting them to fit well on a ship, truck, or railcar.

By using respective modes in the most productive manner, the line-haul economies of maritime shipping and rail may be used for long distances, with the efficiencies of trucks providing local distribution. The entire transport sequence is now seen as a whole, rather than as a series of stages, each marked by an individual operation with separate sets of documentation and rates. Containers have become the most important component for rail and maritime intermodal transportation, enabling them to interact closely and conferring significant time and cost savings.

Most major ports have been transformed to become container ports with the construction of new container transshipment infrastructures. These infrastructures accommodate containerships, ships built solely for the purpose of carrying stacked containers. For rail, new facilities were also required to handle container traffic as well as specialized railcars. The double stacking of containers on railways has doubled the capacity of trains to haul freight with minimal cost increases, thereby improving the competitive position of railways with regards to trucking for long distance shipments. Road transportation has also adapted to containerization, but the requirements are minimal with chassis able to latch in containers.

Intermodal transport is transforming a growing share of freight distribution across the globe. Large integrated transport carriers provide door-to-door services through a sequence of modes, terminals, and distribution centers. Transportation, in terms of modes and routing, is no longer of much concern for customers, if shipments reach their destinations within an expected cost and time range. The concerns are therefore mainly with cost and level of service. For the customer of intermodal transport services, transportation, and distance appear to be meaningless, but for the intermodal providers routing, costs, and service frequencies are important. Therefore intermodalism and globalization makes specific transport modes less visible to the users but requires move visibility for modal operators to effectively manage.

Transportation Modes and International Mobility

International transportation systems have been under increasing pressures to support the growing demands of international trade and the globalization of production and consumption (Dicken, 2015). This could not have occurred without considerable technical improvements permitting to transport larger quantities of freight and people, and this more quickly and more efficiently. Since containers and intermodal transportation improve the efficiency of global distribution, a growing share of general cargo moving globally is containerized. Transportation is often referred as an enabling factor that is not necessarily the cause of international trade, but a mean over which globalization could not have occurred without.

Because of the geographical scale of the global economy, most international freight flows circulate over several modes. Transport chains must be established to service these requirements, which reinforce the importance of transportation modes and terminals at strategic locations. International trade requires distribution infrastructures that can support its volume and extent. Two transportation modes are specifically supporting globalization and international trade; maritime and air transportation. Road and railways tend to account for a marginal share of international transportation since they are above all modes for national or regional transport services. However, a substantial share of the trade between Canada, United States, and Mexico is supported by trucking, as well as large share of the Western European trade. China with its Belt and Road Initiative has also spearheaded long distance rail transport services across Eurasia.

Maritime Transport

The growth of maritime transportation has been fueled by many issues. First, there is an increase in energy and mineral cargoes derived from a growing demand of developing economies. Second, global value chains have resulted in additional demands for long distance trade. Third, improvements in ship and maritime terminals have facilitated the flows of freight, particularly containerized traffic (Stopford, 2009).

Weight-wise, about 80% of the world trade is carried by maritime transportation, which account for 70% of its value. About half of this trade is handled by large containerships linking producers and consumers along sea lanes. This transportation system is organized around major maritime transport gateways where continental trade converges, namely Shanghai, Hong Kong, Singapore and Busan for Pacific Asia, Rotterdam and Antwerp for Europe and Los Angeles/Long Beach and New York for North America, among the largest container ports in the world (Fig. 1).

Economic development in East Asia has been the dominant factor behind the growth and the changes of international transportation in recent years. Since the distances involved are often considerable, this has resulted in increasing demands on the maritime shipping industry and on port activities. As its manufacturing base developed, China was importing

Figure 1 World's major container ports and sea routes, 2015. Source: *Rodrigue, 2017*.

growing quantities of raw materials and energy and exporting growing quantities of manufactured goods. The outcome has been a surge in demands for international transportation, but also problems of imbalanced trade. The ports in the Pearl River delta in Guangdong province now handle almost as many containers as all the ports in the United States combined.

Air Transport

The role of air transportation in the global economy is substantial as a support for passenger and freight mobility (Bowen, 2010). For the mobility of goods, it accounts for about 13% of the value of international trade with goods of a high value to weight ratio such as electronics account for this preponderance. Further, the fast delivery of parcels from e-commerce, which substantially leans on air transport, is a dominant segment of the air freight industry. Traditionally, freight was carried in the bellyhold of passenger airplanes and provided supplementary income for airline companies. However, specialized cargo-only airplanes as well as specialized air freight carriers are becoming dominant. This goes on par with a level of specialization of airports particularly in the United States, where centrally located airports such as Memphis and Louisville are handling a large share of the freight. Pacific Asian airports such as Hong Kong, Singapore and Incheon have also a significant preponderance as air freight gateways for Asian exports (Fig. 2).

Passenger air travel is linked with the level of economic development and the structure of the regional urban system. While most air travel concerns short distances (less than 2 hours of flight time), international passenger movements are dominated by air transport. There are three major concentrations of airports around which the world's air traffic is articulated: North America, Western Europe, and East Asia. The key airports of these platforms, or rather the main airport cities since many metropolitan areas have more than one airport correspond to the world's most prominent cities and the most important financial centers. Yet, this supremacy is being challenged by new hubs of activity such as Beijing and Dubai. There is a direct relationship between the level of air passenger traffic and the primacy of a city in the world urban system. In some cases, the level of passenger activity is related to a pronounced touristic or resort function of an area (e.g., Las Vegas, Orlando, Cancun, Venice, Palma de Mallorca). Air travel is therefore a complex mix of business, personal and leisure derived mobility (Fig. 3).

Large airport terminals are also seeing a substantial concentration of related activities such as distribution centers, just-in-time manufacturers, office parks, hotels, restaurants, and convention centers. These activities have a notable global orientation in terms of their customer base.

Logistics: Producing, Organizing, and Managing Transportation Modes in a Global Economy

The complex web of global production, transportation, and consumption requires managerial efforts. Logistics is the series of activities required for goods to be made available on markets. This mainly includes purchase, orders processing, inventory management, and transportation. As the range of production expanded, transport modes adapted to new demands in freight distribution where the reliability and timely deliveries can be as important as costs. Logistics has consequently taken an increasingly important role in the global economy, supporting a wide array of value chains. First, improvement in transport efficiency expanded the geographical range of value chains. Second, the wide diffusion of information technologies allowed corporations to establish a better level of control over their value chains. Third, technological improvements such as intermodal transportation, enabled an increased continuity between different transport modes and thus within value chains.

The results have been a decrease of the friction of distance and a spatial division of production. This process is strongly imbedded with the capacity and efficiency of international and regional transportation modes, especially maritime and land routes. It is becoming rare for the production stages of a good to occur at the same location, even within a region. Consequently, value chains are integrated with transport modes with logistics as a strategy used to reduce time. For instance, value chains are also becoming increasingly managed by demand, implying that what is being produced is done so to match as closely as possible to what is being consumed. Logistics services are becoming complex and time-sensitive to the point that many firms are subcontracting parts of their distribution activities to specialized logistics providers operating their own modal assets.

An important aspect in the development of transportation modes concerns their manufacturing, which has taken a global dimension. The manufacturing of vehicles such as cars or trucks is mostly for regional use, but the sourcing of parts is commonly global with a propensity to cluster around major assembly plants. Further, exports of assembled vehicles to foreign markets is substantial for vehicles manufactured in Germany, Japan, and Korea, underlining a high level of globalization for both manufacturing and distribution. For aircraft manufacturing, one of the most complex and advanced engineering achievements, centralized final assembly plants, such as in Renton and Everett (Washington, United States) for Boeing commercial jets, are using parts supplied by thousands of manufacturers across the world. The end products have a global market as 70% of Boeing sales concerns customers outside the United States. In a similar fashion, Airbus assembles most of its planes in Toulouse (France) and Hamburg (Germany) from parts mainly provided from across the European Union. For the maritime shipping industry, 90% of the shipbuilding takes place in China, South Korea, and Japan, for conveyances that are used for long distance freight distribution.

Conclusion: Transportation Modes in a Globalized Economy

Globalization has been supported and expended by the development of modern transport modes. From large containerships to cars and delivery trucks, distribution systems have become closely integrated linking manufacturing activities with global markets. However, the 21st century brings many challenges to the role of transportation modes in the global economy. The capacity of many segments of transport system has been stretched by additional demands tying up long distance transportation modes supporting the mobility of passengers and freight. Congestion in many international transport terminals such as ports often causes delays and unreliable deliveries, and there is an acute need for improving inland transportation systems, notably those linked to the major gateways of the global economy. At the urban level, congestion, which is a local phenomenon, is often associated with regional and global distribution such as e-commerce. While developed economies have been able to provide substantial resources in coping with modal demands, many developing economies are facing challenges to provide infrastructures able to support an ongoing demand.

Introduction

From sprawling metropolises, where cars dominate, to medieval city centers, where most residents walk, there are big differences in how people choose to travel in different cities and regions. This chapter explores the range in types of urban travel around the world. Although there is often substantial variation in mode choice within metropolitan areas—most people in Manhattan use transit while most people in suburban Westchester drive—we focus our discussion around the most common modes and some of the common features that help to define and differentiate the cities that rely on them.

The remainder of this chapter is organized as follows. First, we present a general theory of where and why transportation mode varies. Next, we provide an overview of the world's various and varied automobile, transit, motorcycle, cycling, and walking cities. Last, we conclude with a summary of the chapter and discussion of the future of mode choice and cities.

A Theory of Mode Choice in Cities

Since Daniel McFadden's seminal work combining utility theory and qualitative choice modeling, random utility modeling has dominated estimations of whether and how people choose to travel to work, recreation, and other activities (McFadden, 2001; 1974). Increases in computing power have helped to contribute to a number of innovations, such as jointly estimating choices of housing location, activity participation, and mode choice (Ben-Akiva and Bowman, 1998). Nevertheless, the basic theory remains the same. People choose the mode that best suits them. Researchers can observe some of many of the factors that help shape individuals' mode choice, such as income and the relative cost of different modes, but others, such as personal preference, often remain obscure. In random utility modeling, the probability of a person choosing a mode depends on the probability that the unobserved utility, or random error, outweighs the estimated utility based on the observed factors about the trip, person, and available modes. Fundamental to the modeling framework is the assumption that people choose the option that provides the highest utility.

In previous work, we have argued that accessibility—quite simply the ease of reaching destinations—is the most important urban commodity from a resource allocation perspective (Duranton and Guerra, 2016). As evidence of this importance, households generally spend half or more than half of their income on housing and transportation. Housing location determines the distance, cost, and convenience to destinations throughout the city by different modes and transportation spending reflects the trips undertaken by different modes to access specific activities. Although defining and measuring accessibility has empirical as well as conceptual challenges, accessibility is high where residents can reach a wide variety of destinations, which are physically close and for which the cost of travel per unit of distance is low. A lack of accessibility is instead characterized by a paucity of destinations, long distances, and high transportation costs per unit of distance. The concept of accessibility also has close ties to utility, with the estimated utility from mode choice models proposed as a measure of individuals' accessibility to specific activities (Ben-Akiva and Lerman, 1979).

Urban form, the population, and public policy interact to shape which modes are likely to provide the best accessibility for the most people. Urban form, for example, directly shapes the relative attractiveness of different modes. Driving and finding parking in downtown Manhattan are generally costly and time-consuming. Transit services are regular, reliable, and inexpensive. In suburban

Westchester, by contrast, driving is relatively fast and inexpensive. Transit, by contrast, only serves specific destinations and is relatively slow and unreliable. Even accounting for costs, trip distances, and travel times, people are likelier to choose to walk, cycle, or take transit in cities and neighborhoods that are denser, more diverse, and more human-scaled (Ewing and Cervero, 2010). However, cities influence far more than the relative attractiveness of a given mode for a given trip. Cities are the physical environments where people live and must travel to interact with others. There are many components to this physical environment and they interact in a complex manner. For example, a new rail system in a densely populated city with good bus service will almost certainly attract more riders than a new rail system in a sparsely populated city with limited bus service.

Cities also change slowly over time. The investments, policies, and technologies of the past often have as much or more influence on accessibility than contemporary policies, households, or firms. For instance, Brooks and Lutz (2019) show that in Los Angeles the influence of the streetcar on patterns of urban density within the city remains conspicuous to this day, even though the streetcar started its decline as the dominant mode of transport after 1920 and the last piece of streetcar track was dismantled in 1963. More generally, contemporary urban form often relates most strongly to the transportation technologies during past periods of growth (Muller, 2004). New York, London, and Paris' impressive transit system's and transit-oriented development patterns were largely put in place a hundred years ago. Even the depopulating effects of US urban highway investments (Baum-Snow, 2007) are a half-century-old legacy in many US cities.

In terms of the population, household wealth is perhaps the most strongly associated with mode choice. As people get wealthier, they are likelier to move from inexpensive but slow modes, like walking or bicycling, to faster modes like transit, motorcycles, or cars. That said, many of the wealthiest cities have high rates of walking and bicycling. Similarly, even the poorest households rely on cars where sprawling cities and suburbs tend to have long trip distances and unreliable transit services (Blumenberg and Thomas, 2014; Boschmann, 2011; Giuliano, 2005). Those without cars tend to move to job-rich areas with better public transit (Glaeser et al., 2008) or borrow cars from neighbors or friends (Blumenberg and Smart, 2014; Lovejoy and Handy, 2011; Rogalsky, 2010). Other factors, like age and gender, are strongly associated with mode choice in some contexts but not in others. For example, although women are less likely to cycle than men in most cities and countries, there is little difference in cycling rates by sex in countries with high overall bicycle use, such as Germany, Denmark, and the Netherlands (Pucher and Buehler, 2010). The cycling gender gap appears to diminish with the quality of infrastructure (Emond et al., 2009; Garrard et al., 2008; Pucher and Buehler, 2008).

Finally, public policy plays an important role in mode choice. Low fuel taxes, minimum parking requirements, and unpriced roads increase car use in the United States (henceforth, US). High fuel taxes, no on-street parking, and substantial transit investments reduce car use in Japan. Public policy may be particularly important for achieving high rates of cycling in the wealthy cities and countries where cycling captures substantial mode share (Forsyth and Krizek, 2010; Pucher and Buehler, 2008).

Cities and Travel Modes

The following section describes some of the key characteristics of the world's automobile, transit, motorcycle, bicycle, and pedestrian cities. Quite simply we define an automobile city as a city where most people drive and, by extension, the automobile provides the best accessibility for the most people. A pedestrian city is a city where walking provides the best accessibility for the most people. Although this simple definition masks much of the complex nature of accessibility and the complex interactions between urban form, people, and public policy, it also gives us the opportunity to quickly summarize the wide range in mode choice across the world's diverse and complex cities and metropolitan areas.

Automobile Cities

Automobile cities tend to have long trip distances, low-density development, substantial amounts of roadway, high travel speeds, and near-ubiquitous free parking. These situations characterize most the US, where cars capture four-fifths of all trips and nearly nine-tenths of work commutes (US Department of Transportation, 2017). Of the 13% of workers, who walk, bike, or take transit to work, nearly all come from the largest, densest cities in the country. Across the hundred largest metropolitan areas in the US, the car continues to capture 88% of typical work commutes. Even in metropolitan New York, 60% of all commuters get to work by car. In the next largest metropolitan areas of Los Angeles and Chicago, the car captures 89% and 83% of all work commutes. Only in the central cores of US cities do transit and walking capture more trips than cars. In large Mexican urban areas, by contrast, the car captures less than a third of all commutes (Guerra et al., 2018). Consistent with our theory, car travel is substantially more convenient in the US than in other countries. For example, average residents of large US metropolitan areas travel at about 40 kilometers per hour (Couture et al., 2018), compared to 15–25 kilometers per hour in Indian cities (Akbar et al., 2019), 20 kilometers per hour in Bogota (Akbar and Duranton, 2017), and 12 kilometers per hour in Mexico City (Guerra, 2014).

Car ownership and car use have also been increasing substantially in other parts of the world, with China surpassing the US as the world's largest car market (The Guardian, 2010). In Mexico, for example, the size of the vehicle fleet in the largest metropolitan areas grew six fold from 1980 to 2010 (Montejano et al., 2019). As in the US and Europe, car ownership and use tend to go down in China and Mexico's densest cities and those with the least roadway and best transit supply (Guerra et al., 2018; Sun et al., 2017).

Transit Cities

There is a common saying in transportation planning that mass transit needs mass. For a public bus to make sense from an economic and environmental perspective, there need to be enough people going along the bus corridor to fill the bus seats. High-capacity systems, such as subway, light rail, and bus rapid transit (BRT), need even more passengers and thus an even greater mass of people living and working around stations. For the most part, cities in the developing world have mass, in terms of density as well as size. In Mexico City, for example, even the most remote suburban neighborhoods are dense enough on average to support high-capacity subways and metros (Guerra, 2014). In fact, many suburban neighborhoods are as dense as or denser than typical downtown neighborhoods.

There is no shortage of large, dense, and fast-growing cities. In fact, some of the fastest global population growth is happening in the largest cities, particularly the lowest-income ones. Nearly 350 million new residents will live in low and middle-income metropolitan with more than 5 million residents by 2030 (United Nations Population Division, 2014). Cities with 1–5 million residents, which are certainly large enough to support high-quality mass transit systems, are projected to add another 250 million residents. In total, 45% of the developing world's urban residents will live in cities with a million or more residents by 2030. These places are generally ideal locations for developing and strengthening transit use. While regular buses are more appropriate for smaller cities that often rely heavily on them, BRT systems offer a greater capacity and are suitable for cities in the 1–5-million range. High land costs—generally only found in the largest and relatively wealthier cities—are needed to justify the expense of going underground with subway systems.

While larger, denser cities tend to have higher transit use, smaller cities often rely heavily on transit as well. In Mexico, for example, workers use transit to get to work 37% of the time in metropolitan areas with between 75,000 and 200,000 residents compared to 51% in those with more than 200,000 residents. As in other parts of the world, many these workers rely primarily on privately provided transit in minivans and minibuses, with varying levels of service quality and official regulation. Researchers often refer to these services collectively as informal transit or paratransit, and locals use local names such as *angkots*, *mutatus*, or *peseros*, which describe specific vehicle types and services. Although frequently criticized for low vehicle standards and high emissions, these informal transit services are often the workhorse of public transportation. For the 1.25 billion residents of low- and middle-income countries with fewer than 300,000 residents, they are frequently the only available form of public transportation and a major source of employment. They also matter in large cities and those with extensive high-capacity transit networks. Across a score of large African cities, 36%–100% of public transit travel is on informal paratransit. In two-thirds of these cities, more than 80% of public transit is on informal paratransit (Behrens et al., 2016). In Mexico City and Bogota, half of motorized trips involve some form of minibus or minivan transit. Even in New York, dollar vans carry more than 100,000 passengers a day (Correal, June 8).

Motorcycle Cities

In many cities, motorcycles, mopeds, and other motorized two-wheelers have come to dominate the transportation system despite their sometimes uneasy and dangerous coexistence with other motorized vehicles. Asia currently has about three-quarters of the global two-wheeler fleet, and motorcycles are the primary mode of transportation in cities, such as Taipei, Ho Chi Minh City, and Hanoi. Small- to medium-sized Asian cities, which tend to have narrow streets, limited parking spaces, poor transit, and short trip distances, are particularly reliant on motorized two-wheelers. Solo, an Indonesian city of 500,000 to 600,000 residents, is an example of one such city. Between 2009 and 2013, the number of registered motorcycles more than doubled from 208,000 to 424,000—nearly one for every man, woman, and child. As in many other Indonesian and Vietnamese cities, rising incomes, inexpensive motorcycles, easy credit, and low fuel prices helped encourage a rapid increase in motorcycle ownership and use. Millions of others live in cities like Solo, where transit service is poor, transit use is low, and the cost and convenience of motorcycles have made them the mode of choice.

Motorcycle ownership and use have also been growing in a number of Latin American and African cities (Law et al., 2015). Motorcycle taxis are an important component of the transportation system in African cities such as Douala, Lagos, and Ouagadougou. In Jakarta, motorcycle owners can use the smartphone application Go-Jek to provide taxi services in a similar way to car owners with Uber or Lyft. Motorcycle use is sometimes thought to follow a Kuznets curve, where use increases with income up until a certain income level before decreasing as more households switch to driving cars. In the 1960s, many poorer European countries had larger motorcycle fleets than car fleets, much like in Asia today (Nishitatenno and Burke, 2014). Some European cities, like Rome, remain famous for high rates of motorcycle use. Despite substantially higher incomes than in Vietnamese or Indonesian cities, Taipei remain a motorcycle city. Given the relatively efficient way that motorcycles use road capacity—comparable to low-capacity transit vehicles in many cases—an income-driven shift from motorcycles to cars would likely produce substantial amounts of roadway congestion in contemporary motorcycle cities.

Bicycle Cities

Bicycles offer another opportunity to increase access to various parts of the city without increasing pollution, infrastructure costs, or traffic fatalities. Many cities in the developing world rely heavily on bicycles. As incomes have increased and the costs of cars and motorcycles decreased, however, bicycle use has decreased in many parts of the world. In Beijing, for example, bicycle mode share decreased sharply, from 54% in 1986 to 23% in 2007 (Zhang et al., 2014). Nevertheless, rising incomes do not necessitate a decrease

in bicycle use. Cities such as Amsterdam and Copenhagen prove that a city can be modern, wealthy, globally connected, and bicycle reliant. The Netherlands, Denmark, and Germany took active steps to make cycling convenient, comfortable, and safe (Pucher and Buehler, 2008). As a result, women and older adults are just as likely to bike as young men, who dominate cycling in the US and Great Britain. Cities such as Bogota and Buenos Aires have seen increased cycling rates as a result of investments in cycle tracks and bicycle paths.

Pedestrian Cities

For all the emphasis on cars and transit, walking remains the most globally important mode of transportation. Nearly everyone walks, even if just to get from the front door to a car parked on the street. Walking rates are particularly high in small, compact cities with low household incomes and walkable historic cores. These cities are common in Africa and South Asia and also in wealthier parts of Latin America and East Asia. Globally, almost 40% of all trips are made by foot, and the figure is close to 90% in many smaller and poorer cities (Un-Habitat, 2013). Even the largest cities can have high rates of walking. In Dhaka, the Bangladeshi capital of 17 million, more than half of trips are by foot, bicycle, or rickshaw. In Bogota, a relatively wealthy and large city, residents make 43% of all trips by foot. Density and a healthy mix of houses, shops, and businesses make walking an attractive alternative even in peripheral neighborhoods of massive metropolitan areas. In 2030, well over a third of the urban residents of low- and middle-income countries will live in cities with fewer than 300,000 people. Most will rely heavily on walking and other nonmotorized modes of transportation.

Because walking produces almost no local or global pollution, creates no traffic fatalities, costs residents only the food needed to power their legs, has proven health benefits, and requires low infrastructure investments relative to highways or transit, maintaining and encouraging high walking rates are important policy goals. The biggest disadvantage of relying on walking, of course, is the slow speeds. As households earn more income, members often shift to motorized forms of transportation such as cars, transit, or motorcycles that allow them to access more of the city. Unfortunately, as a result many cities and countries neglect pedestrian infrastructure under the assumption that residents will switch to motorized modes if they can afford them (Cervero et al., 2017).

Summary and Conclusions: The Future of Mode Choice and Cities

This chapter offered a general theory of where and why transportation mode varies. We then described some of the key characteristics of the world's automobile, transit, motorcycle, bicycle, and pedestrian cities. We now conclude with a brief discussion of the future of mode choice and cities in an era of rapid urbanization and the diffusion of new transportation technologies.

Shifts in settlement patterns and new technologies are likely to influence the relationship between mode choice and cities in the coming years. For example, as the global urban population has increased, particularly in low and middle-income countries, so has the process of suburbanization. Most metropolitan areas are expanding geographically more quickly than the population is growing. Although developing world cities are, on average, twice as dense cities in Europe and around seven times denser than cities in North America (Angel, 2012), densities have been declining by about 1%–2% annually (Angel et al., 2010). Based on experiences in wealthier countries, the rise in GDP per capita, and the rapid increase in vehicle fleets, it is easy to assume that as urban residents are getting wealthier, they are choosing to live in larger homes on larger lots in suburban areas and rely more heavily on cars. Yet the average suburban expansion in a developing city bears little physical or socioeconomic resemblance to the typical US or European suburb. Although there are many examples of high-income gated suburban communities, suburbs are generally poor and densely populated in the fast-growing cities of Latin America, Africa, and Asia. In China, suburban residents live in densely populated uniform tower blocks. In Mexico City—which is wealthier, more suburbanized, and more reliant on private cars than most developing cities—wealthier households opt to own cars and live in more central locations with good accessibility. Poorer households tend to live further from the urban center and rely on transit, particularly for longer trips such as commutes to jobs in the urban center (Guerra, 2015). Mass housing policies in many countries, moreover, have contributed to an increased demand for transportation by encouraging large, single-use housing developments on the periphery (Buckley et al., 2016). Improving transit in suburban neighborhoods is one of the key challenges for cities in the 21st century.

New technologies, such as smartphone-enabled ride-hailing services, have already had significant impacts on cities and transportation systems. Gorbach (2019) shows that ride-sharing services led to more restaurants to open and rents to increase in previously less accessible neighborhoods. Hall et al. (2018) provide evidence that ride-sharing and transit may complement each other. The effects of new technologies will likely strengthen over time. In the future, for example, self-driving cars could fundamentally alter how people travel—whether by car or transit—and have substantial spillover effects on cities. In some circumstance, particularly in wealthy cities with high driving rates, driverless vehicles will likely lead to an increase in the total amount that residents drive and could also eat substantially into transit mode share. In others, automated vehicles could substantially improve the quality of transit services by providing higher frequencies in smaller vehicles and serving lower-demand trip patterns more effectively. In the long run, self-driving cars could also vastly reduce the amount of space dedicated to parking. With more than twice as much parking as vehicles, most parking also sits idle, consuming space that could otherwise be used for housing, offices, or open space. On the other hand, there will be a long, complicated transition where self-driving and human-driven cars will coexist and may combine the inconvenient of both worlds with a lot mileage for users of self-driving cars and the poor driving conditions created by human-driven cars.

Where does that leave us? Rising incomes in many parts of the world strongly push towards an increased use of individual motorized modes of transportation. At the same time, motorized vehicles generate many undesirable effects, such as traffic collisions, pollution, substantial land consumption, congestion, and busy roads. The massive electrification of vehicles could substantially reduce local and global pollution. This will take time, even more so in developing countries where existing vehicles are used for longer and the switch to cleaner sources of electricity lags far behind. The dreamed paradise of little to no congestion and a minimal number of traffic collisions thanks to self-driving cars is even further away. At the same time, many cities of the world experience currently significant changes in their mobility with vehicle-sharing services and new types of vehicles like electric bicycles and scooters. These changes currently appear chaotic, but they are potentially rich in promise.

We would like to draw two broad policy lessons from all this. First, there is no silver bullet, but complementarities abound. In more developed cities, better transit may be appropriately complemented by congestion charging, the expansion of ride-sharing services, and the development of various forms of micromobility. Poorer cities need to think about both their hard transportation infrastructure as well as their soft transportation infrastructure such as the enforcement of traffic rules. Creating high-quality pedestrian environments and better road-based transit services are particularly important. Second, in urban transportation like elsewhere, one size does not fit all. Cities vary a lot in their urban form and levels of developments. The optimal policy mix is unlikely to be the same everywhere. European cities may envision their development centered around transit. The challenge is obviously very different for most US cities where trip distances are long and even the poorest residents mostly rely on private cars.

Acknowledgments and Further Reading

This chapter draws substantially on [Cervero et al. \(2017\)](#) and [Duranton and Guerra \(2016\)](#). Please consult these works for further reading on cities, accessibility, and mode choice.

Introduction

Remote areas are usually defined as places far away from cities and major centers of population that are difficult to get to (see, for instance, Collin English dictionary). In geographically remote areas of the world, both in the Global North and the Global South, transportation modes tend to be limited by the deficiencies in infrastructure that commonly define and characterize such places located far from cities and densely populated areas. There are two aspects to this poverty of accessibility: firstly, access to the remote area from more populous regions and, secondly, movement within it. Firstly, considering entry to the remote area, immediate access to remote islands—Tristan da Cunha or Easter Island, for example—will be restricted to sea and air transport modes. Access from populous areas to particularly remote locations in the major land masses of the Global North (such as Alaska, the Scottish highlands, or the Urals) or the Global South (where remote locations are a significant feature of every continent) can encompass more diverse transport modes: road and rail may feature in addition to sea and air transport. However, transport services—both passenger and freight—connecting the remote area to major population centers are likely to be limited as a consequence of the remoteness of the location, even if the area possesses a particularly valuable resource, or is of particular strategic significance.

Within these remote locations, wherever they are sited, there are commonly further challenges to mobility: interconnections linking different places within the area will typically be sparse, being underserved by transport infrastructure such as roads, railways, navigable rivers, and airports. Moreover, it is important to note the low service density—incidence of hospitals, schools, banks, administrative services, shops, market centers, and suchlike—that also commonly characterizes remote areas. These deficiencies in facility provision are inextricably linked to the low population density that helps keep such areas “remote” and to the fact that remote area interests are usually further disadvantaged through having less political clout than urban centers. Low service density, coupled with a shortage of cheap, reliable transport, can impact massively on people’s health, education, livelihoods, and general well-being. The combination of poor services and poor transport is often pernicious, promoting a spiral of poverty with intergenerational implications, evident in such diverse locations as the Amazon basin lowlands, Africa’s Sahelian plains, the Highlands of Scotland, and the forests of Rumania’s Carpathian Mountains.

In both the Global North and South, even very remote areas may be crossed by a few major land transport routeways—perhaps an all-season interregional highway or major railway. Minor settlements in the Global North are often connected to such highways by poor but still motorable single-track all-season roads. In many of the more extensive remote areas of the Global South, a majority of within-area transport connections between settlements are dependent on footpaths and minor, unsurfaced, seasonally impassable roads. This tends to reduce viable transport modes in the latter context to foot traffic, draught animals, bicycles, pushcarts, four-wheel-drive vehicles, motorcycles, light aircraft, and drones. Standard motorized transport that dominates in cities—cars, minibuses, and buses—cannot easily negotiate the poor infrastructure that characterizes remote areas: high maintenance costs and frequent breakdowns limit their use.

This entry focuses on transport modes in remote areas with particular attention to Africa because this is where the problem of limited access to transport infrastructure and consequent unavailability of low-cost, efficient transport modes for travel (over more than a few kilometers) is particularly severe. Regional estimates made in 2006 suggest that only 30% of rural people had access to an all-season road in sub-Saharan Africa, compared to 54% in Latin America and the Caribbean, 58% in South Asia, 75% in Europe and Central Asia, and 86% in East Asia and the Pacific (excluding data for China) (Roberts et al., 2006).

Lack of access to transport has enormous impact on the well-being of resident populations because of the particularly low density of health, education, market, and administrative services (World Bank, 2016). When transport services are sparse, competition

between and within modes is limited and costs per kilometer for motorized transport are inevitably high, unless subsidy is available (a rare occurrence in sub-Saharan Africa). Resident populations—already predominantly living at or below the poverty line—suffer accordingly. Women and children tend to experience such deficiencies particularly strongly for they are usually the least well resourced and thus the least able to afford motor-transport fares. Moreover, in some contexts, especially in low-income countries, the association of women’s improved personal mobility with a perceived increased potential for empowerment—or promiscuity—may be an underlying factor shaping (negative) male attitudes to women’s travel.

The paper is structured as follows. Measuring levels of remoteness and (in)accessibility to transport services is inevitably a major challenge in remote areas and is considered first below, before reviewing, in turn, the principal transport modes currently available to rural residents of remote areas: pedestrian travel, cycling, conventional four-wheel motorized transport (cars, minibuses, and trucks), and motorcycles. In each case, freight transport is considered alongside passenger movements. Final sections reflect on the potential of ICT and drones to alter the mobilities landscape of remote areas and the thorny issue of subsidy in the transport services arena.

Measuring Remoteness and Inaccessibility

Given the scale of the remoteness and accessibility problem in Africa (associated with much lower population densities than those prevailing in other world regions), much recent work has, unsurprisingly, focused on trying to establish detailed data for the continent that will improve on estimates of accessibility produced in 2006 by Roberts et al. (noted earlier). A study combining contemporary population count data with detailed satellite-derived settlement extents to map population distributions showed the average per-person travel time to settlements of more than 50,000 inhabitants to be around 3.5 h, with Central and East Africa displaying the longest average travel times (Linard et al., 2012). Subsequently, a new Rural Access Indicator (RAI)—a key global development indicator in the transport sector—has been developed by the World Bank (2016), utilizing new technologies and high-resolution population distribution data. This demonstrates the high correlation between poverty and areas with low road accessibility in a pilot in eight low-income countries in Africa and Asia. Although the RAI only measures the relationship between population distribution and road condition rather than transport services per se, it shows the share of the population that lives within 2 km of the nearest road “in good condition” in rural areas (i.e., an all-weather road as assessed in transport engineering terms), based on the widespread recognition that the 2 km threshold represents a reasonable distance for people’s normal economic and social purposes. In the eight pilot countries (six in eastern Africa, plus Bangladesh and Nepal), approximately 174 million people were estimated to be without road access: in terms of transport modes, this means they are likely to be dependent principally on pedestrian travel. At most, they may have access to a bicycle or—an increasing trend over the last 2 decades—a motorcycle. If Intermediate Means of Transport (IMT) such as push trucks and bicycles are available, they are often seen as men’s equipment: women’s use may even be culturally prohibited, especially where draught animals are concerned, but more often women simply do not have the financial means to purchase IMTs.

Pedestrian Travel

In remote areas of the Global South, especially parts of sub-Saharan Africa where population densities are particularly low, pedestrian travel dominates: for the most part this is a walking world. Rarely, there may be a paved all-season highway touching the area along which occasional conventional motor transport services travel, but most vehicles will speed through without stopping, on their way to major population centers outside the region. Beyond such a highway there are likely to be only unpaved roads and paths and very little in the way of conventional motor transport services. The impacts on children and women tend to be particularly severe.

The majority of children will walk to primary school here, sometimes over long distances: a factor that contributes to late enrolment, truancy, and early dropout, especially when coupled with household labor demands, including children’s pedestrian transport of goods (e.g., water and firewood for domestic use, agricultural produce to local markets). Secondary schools are sparse in remote areas and, when the only option is a very long walk, girls are generally unable to attend because of parental fears that they may be attacked on journeys between school and home (Porter et al., 2017).

Women’s health also tends to suffer significantly in remote locations, especially maternal health and emergency obstetric care (in this case affecting even women of relatively high socioeconomic status). Babies are still regularly born along the roadside as women about to give birth trek to the nearest health center. Knock-on impacts of poor access to maternal health services in remote areas of Africa not only include some of the world’s highest rates of maternal mortality but also long-term health conditions, notably obstetric fistula which affects all aspects of women’s lives by keeping them virtually isolated from their communities (Ehiri et al., 2018).

Such high dependence on pedestrian transport in Africa’s remote areas has a wider negative influence when it comes to freight, which has to be headloaded to more accessible locations where motor transport is available: culturally, this is often designated women and children’s work. Given the high incidence of poverty, even available motor transport may not be utilized and extremely long distances traversed with loads of up to c. 50 kg or even more. This further impacts negatively on the health status of pedestrian load carriers (Porter et al., 2013).

Cycling Modes

Cycling offers a relatively low-cost means of personal travel and transport of smaller loads for residents of remote areas (using a luggage rack or panniers for the latter purpose). However, cycles are still not within the budget of poorer households. In many cultural contexts in Africa, especially more conservative remote rural areas, moreover, cycling is only an option for men and boys. There is evidence from diverse rural areas in Africa of the constraints around girls' cycling, which range from lack of financial resources to purchase a cycle, to girls never having time available to learn to cycle, arguments that only men's cycles with crossbars are available, that men's cycles are too large for women, difficulties of cycling wearing a wrapper (skirt) or with a baby on the back, dangers of girls showing their legs as they cycle, and the potential to sustain gynecological damage by cycling (Porter et al., 2017).

In some remote regions, bicycles also offer a source of income (albeit only for men) through use as a taxi, when fitted with reinforced forks, stronger brakes, a passenger seat, and footrests. Bicycle taxis known as "boda boda" reportedly originally developed spontaneously in the Kenya–Uganda border area (hence the name) in the 1960s but became widespread across Uganda and western Kenya (where they have, to a considerable extent, been superseded by motorcycle taxis that bear the same name). In Malawi, where incomes are lower, bicycle taxis are still an important source of livelihood in remote rural areas, operating between small market centers and off-road settlements. In areas where there is insufficient demand to support conventional motor services they provide an extremely valuable service but, interestingly, in West Africa bicycle taxi services have always been much less common than in eastern Africa.

Various efforts have been made by external organizations such as the World Bank to promote use of cycle-trailers to aid load carriage in poorer remote areas in Africa and Asia. However, these have generally failed despite their apparent potential. In Ghana, for instance, failure of one such project was blamed on bad workmanship in construction of the trailers (which were required in a hurry) and specific difficulties with the hitch mechanism when the carts were heavily loaded, while twisting and breakage of cartwheel rims was attributed principally to the poor condition of local roads. The fact that the bicycle carts tend to need a track width of at least 1 m is a further factor militating against their widespread adoption in remote areas.

Conventional Motorized Transport (Cars, Minibuses, Buses, and Trucks)

In remote areas, conventional motorized transport tends to be sparse beyond any rare all-season road. Population density and low purchasing power of the remote area together act as a powerful constraint on the potential for bus and lorry hire services to be established (unless public subsidy occurs). In many contexts, it is simply not profitable to operate either from or into remote locations, due to insufficient demand and the fact that ordinary motor vehicles cannot easily navigate unsurfaced tracks, especially in wet conditions. Levels of wear and tear on unsurfaced roads are such that maintenance costs that are extremely high: tyre life, for instance, may be reduced by 25%–50% of normal life. Additionally, there will be reduced fuel efficiency, reduced vehicle utilization due to lower speeds, and an overall reduction in vehicle life. Unsurprisingly, where minibus services operate in such areas, fare prices per kilometer are often double or more those prevailing on good paved roads. Meanwhile in the trucking sector, cartels among those operators working along any international corridors that traverse the remote area may facilitate receipt of substantial profit margins even after high-operating costs are taken into account (Teravaninthorn and Raballand, 2008).

Motorcycle Transport (and Its Facilitation by Mobile Phones)

Motorcycles now form a key mode of transport in remote areas of low-income countries in Asia and Africa, often even in countries (such as Ghana) where they are currently illegal (Bishop and Barber, 2018). Up to about 2 decades ago, motorcycle usage in sub-Saharan Africa was very low in many remote areas and often limited mostly to government services (as exemplified by Ghana Ministry of Health supply of motorcycles to its staff involved in outreach in remote areas). Purchase costs were too high for the majority of rural dwellers and spares were rarely available.

Since that time motorcycle uptake has expanded rapidly in many remoter areas, due to the growing availability of cheap imported machines from China and India and the benefits that motorcycle usage offers for improving passenger services and short-haul of goods, particularly on routes where road conditions are inadequate and/or demand insufficient to support regular conventional motor services. Such benefits, once they are coupled with the ready availability of low-price motorcycles, have promoted a massive uptake of motorcycles as a business venture, that is, as motorcycle taxis, used mostly for passenger transport. The facility of motorcycles in moving through narrow paths and tracks where conventional transport cannot pass, means they can also be used for transporting freight (e.g., crop harvest) from farm to home and/or main consolidation points.

This expansion, which gathered pace first in the 1990s in south Asia, then from the turn of this century in Africa, is still ongoing in remoter areas and has been significantly promoted by the expansion of mobile phone networks and the widespread acquisition of handsets, even in poor rural households, over roughly the same period. It is thus possible to call transport to the house, as opposed to walking or taking a bicycle to the nearest major road junction to try to find transport. For the first time in African rural transport history many—even very poor—residents of remote rural areas have the potential to summon transport when they need it. Even if people cannot afford transport on a regular basis, many can now obtain it in emergency contexts. Despite concomitant growth of motorcycle-related accidents, this improved access to transport is of vital importance to the well-being of residents of remote

locations. These new connectivities associated with the expansion of motorcycle taxis and mobile phone networks look set to dominate inter-settlement travel in many remoter rural locations across Africa, in particular, for the foreseeable future.

Although fares are commonly higher than for other transport services, motorcycle taxis are not only reaching remote villages where there is no alternative service, but services are often stationed within those villages (rather than being limited to base stations at the paved road, as has tended to be the case with conventional motor taxis). Conventional taxis usually do not find it profitable to operate from or into remote locations due to insufficient demand and the fact that conventional four-wheel vehicles cannot easily negotiate unsurfaced tracks, especially in wet conditions. Motorcycle taxis thus commonly act as feeder services, linking off-road villages to other (cheaper) motor transport wherever this is available at the paved road.

Motorcycle taxis have also brought new employment opportunities for many young men (though barely any women) in remote areas, even if the motorcycle is owned by a wealthy urbanite. A common practice is for the rider to pay a daily rental to the owner—many can still make a reasonable level of profit. Unfortunately, however, high accident rates (associated with young men traveling at speed and without adequate helmet or other protection) impact not only on the young men themselves, but also on their (usually female) carers and on already stretched medical services.

Driver training geared specifically to motorcycle riders needs urgent attention. Drivers are supposed to be licensed, but corruption in the licensing authorities, police, etc., is so prevalent, in many low-income countries, that a majority of drivers probably operate without adequate training. Helmet usage is often required by law, for drivers, and their passengers, but rarely implemented or adequately enforced. Moreover, it is important to bear in mind that many helmets are of substandard quality and offer little protection (Bishop and Barber, 2018).

Despite the high incidence of motorcycle usage (whether as a commercial or personal transport), insufficient attention is being paid in road engineering to the question of road access conditions where motorcycles are now the dominant transport. Motorcycles need a firm, cambered running surface but can operate along a width much smaller than that required by conventional four-wheel vehicles. There is growing interest in developing appropriate interventions, including a recent pilot in Liberia (funded by GiZ) upgrading footpaths into motorcycle tracks (Jenkins and Peters, 2016). However, since better road surfaces are likely to encourage drivers to increase their speeds, traffic calming measures may be needed in areas around schools, settlements, etc.

ICT in the Transport Sector

As noted earlier, the mobile phone now plays a significant role in improved transport connectivity in remote rural areas of Africa's low-income countries, notably as a facilitator for accessing motorcycle taxis, but also with reference to calling conventional four-wheel transport. This is increasingly feasible as ever more remote areas come within reach of cell phone towers, gradually reducing the coverage exclusion facing low density rural populations located off-road and uphill (Buys et al., 2009). Although the majority of residents in remote areas are poor, many now have access to a basic mobile phone handset and it is standard practice for people—male and female—to keep a selection of local transport operators' numbers on their phone list whom they can call (with calling generally being preferred to text messaging, especially among illiterate populations) (Porter, 2016). The more sophisticated apps that are now helping to support transport service organization in urban areas as smartphone usage grows in many low-income countries are lacking as yet in remote areas. However, rapid developments in the ICT field are such that the current dependence on basic handsets and associated informal organization of transport by phone through personal networks in remote areas could change dramatically over the next decade.

Drones

Drones (pilotless aircraft) are playing an increasingly important role not only in moving cargo into very remote areas in emergency contexts in low-income countries (where restrictions on drone usage are much fewer than in the Global North) but also in gathering information in remote areas that it is impossible or excessively dangerous to reach by other means. When earthquakes and floods occur, land communication is often severely disrupted and the only means of rapid response to the emergency needs of remote populations (light-weight relief items of vaccines, blood, water purification tablets, and suchlike) may be by drone (Rabta et al., 2018). Drones with landing capabilities would have even greater potential: one novel hybrid, for instance, is reportedly being tested by the government's Medical Stores Department in Tanzania with funding from GiZ. This will deliver medical supplies to and from Ukerewe Island, where deliveries are hampered by the infrequency of ferry services (<https://www.weforum.org/agenda/2018/10/drones-for-development-can-deliver-innovation-for-the-whole-industry-heres-how/>). Although disaster relief is currently the most prominent use of drones outside military contexts, drone delivery services look set to be established widely in the near future across remote rural areas, possibly worldwide.

Financing Transport Services in Remote Areas

In high-income countries (and some middle-income countries), subsidy is widely utilized to support transport services in remote areas—this often applies to buses but also can cover other modes, including air services, as, for instance, in the Scottish highlands

and islands and the Remote Air Services Subsidy (RASS) Scheme that forms part of the Australian Government's Regional Aviation Access Programme. In low-income countries, however, governments and donors tend to focus on road building and maintenance as key to improving access to remote areas and assume that a road in good condition is all that will be needed to bring in service providers. Consequently, transport service provision is left to the informal market. In such remote places, however, since poverty levels tend to be high and demand consequently low, it may be necessary to consider the role of subsidy in transport services, though donor resistance is high (despite continued subsidy of road construction).

There is certainly limited experience of formal transport subsidy in Africa, except in South Africa where the cost and complexity of managing transport subsidy interventions, especially in the informal sector, remain significant issues. However, a 6 month action research study in Malawi involving subsidy of daily minibuses from five villages along a good road, with randomized prices to households, showed that, at any price, a bus operator would never make enough revenue to break even on this road (Raballand et al., 2011). This work suggests that motorized services are often likely to need subsidizing in remoter areas; otherwise a road in good condition will most probably not lead to provision of service at an affordable price for the local population.

Hine et al. (2015) draw together a strong argument as to why there is need to provide ongoing financial support for services in the most remote areas of low-income countries. Where motorized passenger mobility is very low they suggest there is a good case to directly subsidize transport services. Local governments could set basic service standards for frequency, capacity, safety standards, routes and timetabling, loading rates, etc., and only providers adhering to those standards would be supported. As they point out, service subsidies would be very modest in relation to road construction costs and the potential for corruption is far lower than in the case of infrastructure investment. Rural road investment programs funded by donors and governments and road funds could be utilized for the subsidies. They also suggest pilots to test the use of ICT-based applications that could help consolidate goods and passenger loads more efficiently and avoid empty trips.

To conclude, the web of connectivity within which the physical transportation sector sits in remote areas of the world has changed significantly over the last 2 decades. Access to transport, whatever the mode, often now depends significantly on ICT, though for populations in low-income countries this means, above all, connection secured through a basic mobile phone. In such contexts, the direct constraints imposed by physical transport infrastructure—roads, in particular—are being reduced substantially in many locations through the expansion of motorcycle usage and now also, to a small extent, drones. However, careful regulation of both motorcycles and drones will be required by governments in order that their potential to improve service access for remote, poor populations is nurtured while at the same time ensuring that safety considerations are adequately observed. Subsidized motorized public transport services could play a valuable complementary role along selected routes, especially to support the mobility of older or infirm people who cannot easily travel by motorcycle. Further improvement of remote area service access by the expansion of e-services—especially e-health—can be expected and could more fully complement all current modes in future years: it is likely that services will, increasingly, be accessed by a fully joined-up mix of physical transport modes and ICT.

Introduction

Mode choice models (sometimes also referred to as modal split models) explain the distribution of a given total freight transport flow over available transport modes: road, rail, waterways, sea, air and pipelines. Mode choice modeling is a vital component of freight transport models and instrumental to predicting future flows and assessing transport policy impacts. In many freight transport models, next to route choice, modal split is a very sensitive demand component, responding more to changes in transport time and cost than transport generation and distribution.

The dependent variable in a mode choice model can be a discrete variable (a choice of one of the modes) or a continuous variable, in the form of a probability or fraction. The latter allows to calculate modal shares for aggregate commodity groups or groups of firms within entire geographic areas. Explanatory variables will most often only include the price of transport by the available modes and the transport time and/or frequency of transports. More recent empirical models will also consider one or more of the following:

- reliability (% of goods delivered on time),
- flexibility (ability to handle short-term change requests),
- risk of damage during transport (% value loss),
- tracking and tracing possibilities of the cargo, and
- emission of noise and harmful gases or particles.

The sensitivity of modal choice to these attributes will differ between different commodity types (e.g., bulk versus general cargo), shipment sizes, industries, firm sizes, transport equipment used (e.g., containers) and geographic distances. The modes available will usually differ, depending on the geographical scale of the model. Different modes of transport have very different properties in terms of their broader economic and environmental impact, requirements on public funding and safety.

A key distinction in freight mode choice modeling is that between aggregate and disaggregate models. By “disaggregate” we mean here that the unit of observation is the individual decision-maker (firms in freight transport) as opposed to “aggregate” models where the units of observation are aggregates of decision-makers, usually geographical zones. The aggregate mode choice model, especially the aggregate logit model, is the most commonly used model for mode choice in freight transport. Disaggregate models, however, are better rooted in theory of individual decision-making behavior.

Mode choice decisions are seldom made in isolation. From logistics management theory and practice, it is well known that, indirectly, decisions about for example, shipment size and distribution channel can play an important role in the mode choice decision. Also for policy makers, it has become important to understand that mode choice cannot be influenced without considering the entire, relevant logistics environment. More and more, therefore, new models are being developed to take these relationships between mode choice and other decisions into account (Combes and Tavasszy, 2016; De Jong et al., 2016; Tavasszy et al., 2012).

In this chapter we first introduce the current theoretical foundation of mode choice models in random utility, discrete choice theory. Subsequently, we present alternative forms for disaggregate (firm level) and aggregate (geographical zone-based) models, and discuss extensions of mode choice models in recent research. We provide lessons from recent examples of recent model applications from the scientific literature and close the chapter with conclusions.

Theory: Mode Choice of the Firm

Below we introduce the theoretical foundations of mode choice models. We refer the reader who is interested in more detailed background material, to De Jong (2014).

We assume that the main decision-maker is the shipper, a firm sending goods to a receiving firm and therefore has a demand for transport services. Shippers have a choice to carry out the transport themselves or to contract it out to a logistics service provider (including carriers and firms that integrate services of different carriers for their customers). The shipper makes mode choice decisions for a flow of shipments. A shipment is defined as a number of units of a product that are ordered, transported and delivered to one receiver; this may be a larger or a smaller volume than one single vehicle load. Alternatives in mode choice can be road transport, rail transport, inland waterway transport, sea transport, air transport, and pipeline transport. An essential characteristic of all these alternatives is that they are discrete (chosen or not chosen, as opposed to the case of continuous variables or ordered choice alternatives).

Discrete choice models at the disaggregate level have first been developed in passenger transport, where the dominant choice paradigm and theoretical foundation is that of random utility maximization, RUM (Ben-Akiva and Lerman, 1985). The basic equation of the RUM model is:

$$U_{ik} = Z_{ik} + \varepsilon_{ik} \quad (1)$$

In which:

U_{ik} is utility that decision-maker k derives from choice alternative i ($k = 1, \dots, K; i = 1, \dots, I$);
 Z_{ik} is observed utility component; and
 ε_{ik} is random utility component.

Utility maximization belongs to the economics of consumer behavior, and seems at first sight inappropriate for explaining the behavior of the firm, where the standard economic paradigm is that of profit maximization or costs minimization. The random utility framework can be applied to freight transport choices by taking the (negative) total generalized transport costs as the systematic part of the utility function and adding a random costs component to this function:

$$U_{ik} = -G_{ik} + e_{ik} \quad (2)$$

In which:

G_{ik} is systematic component of generalized transport cost and
 e_{ik} is random cost component.

In Eq. (2) random costs minimization becomes random utility maximization. For the standard discrete choice models with an independent, zero mean error term and without heteroscedasticity, one might just as well write a plus sign in front of e_{ik} . The mode choice model for freight transport can then be estimated using the same software as for the RUM model in passenger transport. If one assumes negative coefficient signs for the costs variables, one can also write $+G_{ik}$ in Eq. (2), as we will do later.

More specifically, for the choice of mode between three alternative modes i (here road, rail and inland waterways—IWW), one can specify the following linear utility functions:

$$U_{\text{road}} = \beta_0 + \beta_1 \cdot \text{PRICE}_{\text{road}} + \beta_2 \cdot \text{TIME}_{\text{road}} + \beta_3 \cdot \text{REL}_{\text{road}} + e_{\text{road}}, \quad (3a)$$

$$U_{\text{rail}} = \beta_4 + \beta_1 \cdot \text{PRICE}_{\text{rail}} + \beta_5 \cdot \text{TIME}_{\text{rail}} + \beta_6 \cdot \text{REL}_{\text{rail}} + e_{\text{rail}}, \quad (3b)$$

$$U_{\text{IWW}} = \beta_1 \cdot \text{PRICE}_{\text{IWW}} + \beta_7 \cdot \text{TIME}_{\text{IWW}} + \beta_8 \cdot \text{REL}_{\text{IWW}} + e_{\text{IWW}}, \quad (3c)$$

In which:

COST is transport price (monetary units);
 TIME is transport time (hours); and
 REL is transport time reliability (hours).

$\beta_0, \beta_1, \dots, \beta_8$ coefficients to be estimated; we expect negative signs for $\beta_1, \dots, \beta_3$ and $\beta_5, \dots, \beta_8$, the sign for β_0 and β_4 can be positive or negative.

In Eqs. (3a)–(3c), the utility that would be obtained when choosing road transport depends on the transport cost and time for that shipment by road transport and its reliability, and likewise for the other two modes. A key reason for including the alternative specific error components e_{road} , e_{rail} , and e_{IWW} in the utility functions is that these represent important variables that are not observed (well) by the researcher. These may include attributes such as mentioned earlier, for example, concerning risk of damage or availability of tracking and tracing services.

In order to deal with the error components, the researcher assumes that these are random variables. One can derive different discrete choice models with different specific assumptions on the probability distribution of the error components.

Random Utility Models for Mode Choice

The most common assumption for the error components ϵ is that they are independently and identically (i.e., same variance across observations) distributed following the extreme value type I (or: Gumbel) distribution. This leads to the multinomial logit (MNL) model with the choice probabilities:

$$P_{ik} = \frac{e^{G_{ik}}}{\sum_i e^{G_{ik}}} \quad (4)$$

The MNL model can be estimated by Maximum Likelihood methods that do not involve any simulation. Several software packages contain MNL estimation (sometimes called “conditional logit”). The estimated coefficients can be applied on a sample of firms (shipments) to calculate probabilities for all choice alternatives and observations. If this sample is representative of the population studied, one can then simply sum the probabilities (this method is called “sample enumeration”) over all observations in the sample to get the market shares for the alternatives (e.g., the share of road transport in the total for road, rail, and inland waterways) as predicted by the model. For nonrepresentative samples, one can do a weighted summation with the population to sample fractions for each observation as weights. Different zones in a study area or different horizon years might even have different sets of weights. Such applications can give the impact of changing a single variable at a time (which can be expressed in the form of elasticities), but can also predict what would happen in case of an input scenario with changes for several (possibly all) variables in the model. Note that one can correct for the effects of nonrepresentative samples relating to the eventual choice (resulting in underestimation of the share of a mode of transport), by calibrating the alternative specific constants to observed shares in practice.

Discrete choice models estimated on stated preference (SP) data only should not directly be used for forecasting (including the derivation of elasticity values), since the SP data will have a different variance for the error component than real world data, which will affect the choice probabilities. This happens because in the experimental setup of the SP many things that can vary in reality are kept fixed, and vice versa. Therefore, for forecasting it is better to use revealed preference (RP) data or combined SP/RP data where the variance of the SP is scaled to that of the RP. Models estimated on SP data can directly be used to derive ratios of coefficients (such as a value of time or a value of reliability) because in calculating these ratios, the SP error component drops out.

A restriction of the MNL model for policy applications is that the cross-elasticities for competing modes are the same: if the cost of road transport increases, substitution will occur to rail and inland waterways in proportion to their current market shares. Another manifestation of the same phenomenon is the independence from irrelevant alternatives property: the ratio of the choice probabilities between two alternatives does not depend on any other alternative. These properties may be at odds with reality. In practice, there could for instance be more substitution between rail and inland waterways than between any of these alternatives and road transport. One way to avoid this problem is the use of a nested logit model in which alternatives are grouped in a nest, allowing correlation between them. Mathematically, the easiest representation is to distinguish two probabilities, linked to each other by the logsum variable.

$$P_{B_l k} = \frac{e^{G_{ik} + \lambda_l I_{lk}}}{\sum_i e^{G_{ik} + \lambda_l I_{lk}}}, \quad (5a)$$

$$P_{(ik|B_l)} = \frac{e^{H_{ik}/\lambda_l}}{\sum_{i \in B_l} e^{H_{ik}/\lambda_l}}, \quad (5b)$$

$$I_{lk} = \ln \sum_{i \in B_l} e^{H_{ik}/\lambda_l}. \quad (5c)$$

The first probability (5a) gives the chance that decision-maker k chooses an alternative within nest B_l . This depends on the generalized cost G of l plus a coefficient λ_l times the expected cost from the alternatives in the nest, represented by I_{lk} , the so-called “logsum” variable, relative to the same kind of costs for the all alternatives at the nesting level. The second (conditional) probability gives the change of choosing alternative i given that nest B_l has been chosen. This depends on the generalized cost of this alternative relative to those for all alternatives in the nest. The resulting unconditional probability that decision-maker k will select alternative i is:

$$P_{ik} = P_{(ik|B_l)} P_{B_l k} \quad (5d)$$

The coefficient λ_l is the “logsum coefficient” which gives the degree of correlation between the error components of the alternatives in nest B_l : the higher this coefficient, the lower the correlation. In estimation, this is an extra parameter to be estimated. The estimated value must be between 0 and 1 for global consistency (meaning: across the entire range for the exogenous variables) with RUM. If a value above 1 is found, this often is an indication that a different (especially a reversed) nesting structure would work better and be consistent with RUM.

Both MNL and nested logit are members of a family of models, the generalized extreme value family, which is consistent with random utility maximization. Interestingly, most of these have not been applied for freight transport yet, although they offer more flexibility in terms of substitution patterns between alternatives than MNL or nested logit. This includes cross-nested logit, where a single alternative can belong to more than one nest at the same time.

Assuming that the error components follow a multivariate normal distribution leads to the probit model (in the multinomial case abbreviated as MNP). This model is almost as straightforward to estimate as MNL when there are only two alternatives. Probit

models with more than two alternatives lead to multidimensional integrals, and simulation methods can then be used for estimation but this is all (still) relatively cumbersome. On the other hand, the probit model is very flexible, since one can define and estimate specific correlation parameters between the alternatives.

The mixed logit model has two error components $\varepsilon_{ik} + v_{ik}$, where one follows the Gumbel distribution (so that conditional on the other, the model is MNL) and the other can follow any distribution, such as the normal or lognormal. With this technique one can accommodate two ideas, which are both generalisations of MNL: (1) random coefficients, to describe taste variation or heterogeneity in preferences of decision makers and (2) specific correlation structures between alternatives. In practice, for forecasting and transport policy appraisal, the evaluation of mixed logit models is still time consuming. However, several current software packages allow for estimating these models.

An alternative to model heterogeneity is the latent class MNL model, that is related to mixed logit. Within the random coefficients specification, this model uses a discrete number of possible values for a coefficient, instead of one average value. A selection of values remains after estimation, which represents weights of different groups of users. Membership functions link the users to classes. Observable user attributes (e.g., firm size, sector) can be used to analyze class membership patterns.

There have been many applications of the logit model in its different forms, from the early disaggregated SP studies using MNL (Fowkes et al., 1991) to mixed logit work (Arunotayanun and Polak, 2011) and recent latent class models (Duan et al., 2016). Because of the high data acquisition costs, disaggregate mode choice models are often specifically made for submarkets (specific commodity groups, container types, corridors or cities) and are very rarely built to represent an entire national freight market. This is the realm of the aggregate freight models, which we discuss next.

Aggregate Mode Choice Models

The aggregate logit choice model makes us of a different kind of observation than individual choices: the flows of shipments on one and the same origin-destination (OD) zone pair, as distributed across different transport modes. The aggregate modal split model can be explained from the theory of individual utility maximization, assuming that all variations in characteristics of the decision-makers and of the goods are captured by the error component of the utility function. As this is a very questionable assumption, aggregate modal split models can best be seen as pragmatic models with a loose connection to theory of behavior. Nevertheless, they regularly lead to satisfactory empirical results (elasticities, forecasts) at relatively low effort (especially concerning data collection).

Although the model can be expressed with the same mathematical formulation as the disaggregate MNL model, a convenient and classical formulation is the logarithmic or “difference form,” here for the bi-modal case:

$$\log \frac{S_i}{S_j} = \beta_0 + \beta_1 (P_i - P_j) + \sum_w \beta_w (x_{iw} - x_{jw}) \quad (8)$$

In which:

S_i/S_j is the ratio of the market share of mode i to the market share of mode j .

P_i and P_j are the transport costs using these two modes.

$X_{iw} - X_{jw}$ are w ($w = 1, \dots, W$) differences in other characteristics of the two modes.

Aggregate logit models are popular as usually disaggregate data are not available, while national and regional statistics offer good observations of tons by OD zone pair and mode. Aggregate choice models can easily be estimated, producing an intuitively appealing S-shaped market shares curve and market shares between 0 and 1. Depending on the mathematical formulation used, this model can be estimated using the discrete choice estimation software for disaggregate models or by standard regression analysis. Because of these advantages, the aggregate logit model still is the single most used model specification in practical freight mode choice modeling, especially in national freight transport models (De Jong et al., 2016). As the estimation of these models relies on data about large flow volumes between regions, the models will perform less well for the modeling of modes with a very small weight share (say, below 5%) like intermodal transport and air transport. For these markets, disaggregate models are better suited.

Alternatives for Random Utility: Prospect Theory, Random Regret, and MCDA Models

The interpretation of discrete choice models as random utility maximization models provides a foundation in microeconomic theory. For some decisions the economic perspective might be more relevant (here one might think of important well-planned long-run decisions, especially in a business context); for other decisions other perspectives (psychological or sociological) might be more important. In recent years, alternative paradigms have gained popularity in transport modeling: prospect theory, regret minimization, and multicriteria decision analysis (MCDA). We discuss these as follows.

Prospect theory, developed by psychologists, posits the following behavioral traits:

- reference dependence—the valuation of an attribute depends on the current value;
- loss aversion—there is a difference in the valuation of gains and losses in an attribute;

- size dependence—there is a difference in the valuation at different values of an attribute; and
- nonlinear weighting of probabilities by respondents.

Regret minimization is based on the assumption of minimization of anticipated regret by decision-makers. Regret occurs when a nonchosen alternative scores better on some attribute than the chosen alternative. When two regret components are distinguished in the regret function, “observed” or “systematic” regret and random regret, this leads to the random regret minimization model RRM. The distributional assumptions for the random component(s) can be similar to those of the RUM model, and even the same software can be used for RRM and RUM, but the choice probabilities from the two types of models will be different. The key difference is that RRM captures the “compromise effect”: alternatives that perform “in-between” on all attributes, relative to the other alternatives, are generally favored over alternatives with a poor performance on some attributes and a strong performance on others. We refer to [Keya et al. \(2018\)](#) for a recent application for freight transport.

Multiple-criteria decision analysis presents a normative approach to support decisions by calculating the relative performance of alternatives using a compensatory and additive performance function, consisting of several criteria and their weights—exactly as applied in utility theory. Some methods in MCDA allow to infer weights for criteria from survey-based experiments, just as in discrete choice modeling. Although it is not rooted in a descriptive theory of choice behavior, the MCDA approach is powerful because of its mathematical and computational simplicity.

Extensions to Mode Choice Models

It is useful to consider integrative modeling of mode choice with other choices, because of interdependencies with other choices in logistics ([Roorda et al., 2010](#); [Tavasszy et al., 2019](#)). For example, in intermodal transport, route choice and mode choice are done simultaneously in a multimodal network with transshipment centers. A less obvious case is the relation between shipment size and transport mode. Unit costs of shipment will be lower for modes with higher carrying capacity. At the same time, lower unit costs of transport will promote a choice for a smaller shipment size, as transport costs will be less important compared to inventory holding costs. These are two counter-balancing (as opposed to mutually reinforcing) influences, suggesting that, theoretically, an equilibrium could be reached that results in minimal total logistics costs. Modeling these choices together allows to search for a consistent overall solution from a total logistics costs perspective. In practical terms, joint modeling of choices helps to embed mode choice models in comprehensive freight transport models. A recent review can be found in ([Engebrethsen and Dautère-Pères, 2019](#)).

The main streams of research here have combined mode choice with shipment size decision and trading decisions, vehicle type decisions, and route choice decisions. The most commonly used approaches are discrete choice modeling, sometimes embedded in network formulations (see, e.g., [De Jong and Ben-Akiva, 2007](#); [Jourquin and Beuthe, 1996](#)). As combined choices in network models go beyond the conventional route and link choice decisions, they are also termed supernetwork models (in case of mode and route choice combined) and hypernetwork models, in cases where nonnetwork related choices are included such, related for example to transport demand volumes and trade partners. Most multimodal network models assume deterministic choice behavior, but examples can also be found of applications of MNL and MNP.

One criticism of such models is that the simultaneity of decisions is not proven easily as in practice, as even very closely related logistics decisions (such as the shipment size and mode choice decisions) are often taken by different managers, reviewed with different frequencies and evaluated in different and often unconnected processes. One may assume that, over time, the aggregation of experiences in a company provides sufficient feedback to all managers in a company to align their decisions better. As there is only scant empirical evidence of this convergence ([Combes, 2012](#)), the construct of simultaneous optimality in decisions remains largely theoretical.

A connected line of research has emerged that recognizes the influence of different decisions-makers within a company and of related decisions in horizontal or vertical interfirm relationships. One line of approach to modeling interactions is the combination of game theory with experimental economics to collect data ([Holguín-Veras et al., 2011](#)). Such economic experiments are often carried out with students in the role of economic agents that interact with each other in various market settings. The advantage is that the stylized models can lead to simple and easy-to-follow processes. Another line of research tries to integrate the idea of interactions into SP survey design and modeling, using the so-called interactive agency choice experiments, a negotiation variant of SP experiments ([Hensher and Puckett, 2007](#)). As survey costs of such an approach will be relatively high, approaches to keep the amount of interactions within bounds are needed, such as minimum information group inference, MIGI. Building on the multiagent direction of thinking, another new line of research is the use of serious gaming as a way to obtain input for estimating choice models ([Kourouniotti and Tavasszy, 2017](#)). Gaming allows a more immersive experience but, at the same time, a less controlled experiment than surveys. In terms of the number a nature of responses of respondents, the deliberation process followed by agents and the choice situations experienced, the results of a game can vary widely. Yet they allow to record responses of a broad group of interacting players, making it interesting for more complex choice situations.

The emerging broader application frameworks for the aforementioned models are multiagent system models, also referred to sometimes as agent-based models. These include an explicit account of the different agents and their decision-making processes. Recent research has taken steps to include discrete choice models as part of this framework ([Le Pira et al., 2017](#)). For an example of an empirical multiagent model of mode choice, we refer to [Reis \(2014\)](#). Future work is directed toward further completion of the framework of multiple logistics decisions around freight mode choice.

Conclusions

In the above we have introduced the current mainstream framework for empirical mode choice modeling: discrete choice, random utility maximization-based models.

We have described the most often applied model variant, the MNL, including its variants. In everyday practice, the aggregate version of the logit model is the one most often applied for national level freight mode choice studies, while disaggregate models prevail for submarkets of the national freight market. Also we have presented some emerging alternatives in the form of prospect theory, random regret minimization, and (descriptive) MCDA models.

Finally, we discussed increasingly popular extensions to mode choice models, which endeavor to embed the choice of mode in the broader context of multiagent, comprehensive logistics decision making. These provide new frameworks for empirical research into mode choice models.

Introduction

Modern, functionally differentiated societies depend on efficient transport systems to bring together their spatially distributed economic, social, cultural, and political activities. Transport science was launched in the 1950s with the aim of providing accurate forecasts of demand for travel (Pas, 1990). It is focused on the following four topics: (1) choice to travel or not, (2) choice of destination, (3) choice of travel mode, and (4) choice of route. These four topics are the pillars of transport policy making and planning referred to as the *four-step model* (McNally, 2007). The present chapter deals with the third step: travel-mode choice. For the other topics see the contributions of xxx in this encyclopedia.

Not least because of the strong political support provided by national governments, the motorized transport system has become the dominant travel mode with particular emphasis on the privately owned automobile. In 2015 worldwide about 1.3 billion cars were used to meet peoples' everyday mobility needs (Wagner, 2018). Offsetting the individual and societal benefits of the motorized transport system is the growing awareness of its serious drawbacks and deleterious side effects (see e.g., van Wee, 2014). At the local level, urban environments have become less livable due to particle emissions, noise, and traffic accidents. Worldwide in 2016 approximately 1.25 million people were killed in road accidents and 20–50 million were injured or disabled (ASIRT, 2019). In addition, road and parking infrastructure infringe on public land and can destroy sites of historical and cultural value with a detrimental effect on overall quality of life. At the global level, the motorized transport system is a major contributor to climate change. Road transportation accounts for about 20% of all carbon dioxide (CO₂) emitted annually into the atmosphere (Bamberg & Rees, 2017). As a result, motorized transit has become a strategic sector for policymakers interested in mitigating climate change. All these effects are societal problems produced by individual behaviors that are reasonable and often well intended from the individual's perspective (de Graaf & Wiertz, 2019).

Technological advances such as electric vehicles could potentially reduce transportation's impact on climate change, yet it seems unlikely that these technologies will be scaled so rapidly that they will have a significant impact on CO₂ emissions in the near term (European Environment Agency, 2018). Moreover, electric cars—like their internal combustion engine counter parts—require an extensive infrastructure of roads and parking facilities. To reduce the negative impacts of motorized transportation, governments and local authorities will therefore have to rely on interventions aimed at motivating people to reduce their reliance on the car and adopt more environmentally friendly means of transportation such as walking, cycling, or use of public transportation. These interventions must go beyond providing alternative means of transportation to change behavior by targeting beliefs, attitudes, and other psychological factors that influence transportation decisions.

Given our present focus on travel-mode choice, we focus on the role of psychological determinants of individual travel-mode decisions, especially car use in comparison to alternative modes of transportation. For this purpose, we introduce in the next section psychological determinants of travel-mode choice within a multidisciplinary framework. The theory of planned behavior (TPB, Ajzen, 1991, 2011) is employed as a general theoretical framework to conceptualize central psychological constructs influencing human decision making, the causal interrelationships among these constructs as well as their intersection with objective socio-demographic, space-related, and journey characteristic as well as contextual attributes like laws and regulations. In the following sections, we summarize the empirical evidence supporting the claim that the TPB provides a useful conceptual framework not only for a better understanding of individual travel-mode choice but also for the development of effective policy interventions (ress) aimed at reducing people's car use. In the final section we discuss limitations of current research and potentially fruitful new theoretical and methodological developments.

Figure 1 A multi-disciplinary approach for structuring modal choice determinants. Source: De Witte et al. (2013).

Psychological Determinants of Modal Choice Within a Multidisciplinary Approach

Figure 1 depicts the *multidisciplinary approach* proposed by De Witte et al. (2013) for integrating the travel-mode choice determinants discussed in the economic, social-geographic, and psychological literature.

On the outside circle, the framework distinguishes among three types of factors or indicators that can influence choice among available travel modes. These factors can be sociodemographic (e.g., age, gender, income, education, car availability), journey characteristic (e.g., distance, travel time, travel costs, departure time), or space-related (e.g., population density, diversity, proximity to infrastructure and services, frequency of public transport, parking). The connections among these determinant types represent the possible interrelations and dependencies that may occur among them (for a detailed discussion see De Witte et al., 2013). Together they encompass the objective travel-related context for a specific trip. The second circle represents the influence of psychological indicators like perceptions, experiences, attitudes, etc. These factors are assumed to determine how the objective possibilities shaped in the first circle are perceived and acted upon. Choice of travel mode (modal choice) is positioned in the middle as the result of the interactions among the sociodemographic, space, and journey characteristics, mediated by the impact of the social psychological determinants. What is missing however is the important influence of laws and regulations on travel-mode choice.

The Theory of Planned Behavior

To explicate the role ascribed to psychological factors in the multidisciplinary approach, a theoretical framework is needed that will provide answers to the following three questions: (1) Which psychological constructs should be viewed as the most important immediate determinants of observable travel mode choice? (2) How are these constructs causally related to each other? and (3) How is the impact of the objective indicators (outside circle in **Figure 1**) on observable travel mode choice mediated by the more proximal psychological indicators?

Over the past three decades the TPB (Ajzen, 1991, 2012, Fishbein & Ajzen, 2011) has become a frequently used framework for answering these three questions. Concerning the first question the TPB, like other cognition-behavior models (e.g., Rogers, 1983; Triandis, 1977), identifies behavioral intention as the most immediate antecedent of behavior. Behavioral intention refers to a person's readiness to perform an action (e.g., "I intend to drive to work"). In addition, the TPB proposes that perceived behavioral control (PBC), that is, people's appraisals of their ability to perform a behavior (e.g., "I have access to a car") may also be used to predict behavior when perceptions of control accurately reflect actual control over the behavior (Fishbein & Ajzen, 2011). Specifically, behavioral control acts a moderator of the intention-behavior relation (La Barbera & Ajzen, 2019; Yang-Wallentin et al., 2004), such that intention predicts behavior well to the extent that behavioral control is high.

Concerning the second question, the TPB assumes that behavioral intention ("I intend to drive to work") is determined by evaluations of the consequences of this action, that is, the attitude toward the behavior (e.g., "Driving to work is good/bad") and by perceptions of social approval of the behavior, termed subjective norm (e.g., "People who are important to me think that I should drive to work"). In addition, the TPB proposes that PBC also bolsters intention because perceived feasibility ("I have access to a car") is usually a prerequisite for motivation to engage in the behavior. Although in most applications of the TPB, attitude, subjective norms, and perceived behavioral control have been treated as independent predictors of intention, in the original formulation of the TPB (Ajzen & Madden 1986), PBC was postulated to moderate the effects of both attitudes and norms on intention (see also Fishbein

Figure 2 Using the TPB for modeling the psychological factors mediating the impact of objective environmental characteristics on observable travel behavior.

& Ajzen, 2011). Research in recent years has provided empirical support for the proposed interactions (see Castanier et al., 2013; Earle et al., 2019; Hukkelberg et al., 2014; La Barbera & Ajzen, 2019; Yzer & van den Putte, 2014).

Concerning the third question, the TPB assumes that beliefs provide the bases for attitudes, subjective norms, and perceptions of behavioral control. Specifically, attitude toward the behavior is based on beliefs about the likely positive and negative consequences of performing the behavior (*behavioral beliefs*, e.g., “driving to work is fast, reliable, and comfortable”), subjective norm rests on beliefs about the normative expectations of important others (*normative beliefs*, e.g., “my spouse approves of my driving to work”), and PBC is based on beliefs about the presence of factors that may facilitate or impede performance of the behavior (*control beliefs*, e.g., “It is easy to find parking near my place of work”). According to the TPB, behavioral, normative and control beliefs build the theoretical bridge over which objective external sociodemographic, journey, and spatial characteristics, considered *background factors*, impact the more proximal travel-mode choice determinants. An effective transport policy intervention must therefore target the behavioral, normative, and/or control beliefs most people associate with using alternative travel modes. For example, to discourage car use and increase biking to work, an intervention could attempt to raise the accessibility of positive outcomes associated with riding a bike and the accessibility of negative outcomes associated with car use. It could also try to raise the perception that important others approve of riding the bike to work and lower their perceived support for using the car. Finally, the intervention could attempt to increase skills or knowledge related to riding a bike and decrease actual barriers or establish facilitators for bike use, such as establishing dedicated bike lanes. Figure 2 presents graphically how the TPB answers the above raised three questions as a conceptual model. It can be seen that background factors (outer circle in the multi-disciplinary approach) are postulated to influence travel-mode intention and behavior indirectly by their possible effects on behavioral, normative, and control beliefs; and that the effects of behavioral, normative, and control beliefs on intentions are mediated, respectively, by attitude toward the behavior, subjective norm, and perceived behavioral control.¹ Finally, the effect to intentions on travel behavior is moderated by actual behavioral control or, when a measure of actual control is unavailable, by perceived behavioral control under the assumption that perceived control reflects actual control reasonably well.

For the sake of simplicity, we have left out in Figure 2 the additional differentiation of attitudes into instrumental and experiential attitudes, of subjective norms into injunctive and descriptive norms, and of PBC into capacity and autonomy factors, as proposed by Fishbein and Ajzen (2011). In addition, we have also omitted feedback loops from behavior to beliefs. It stands to reason that once a behavior has been performed, e.g., when people ride a bike to work for the first time, the experience may well change some of their existing beliefs and introduce new beliefs. For example, they may discover that riding a bike takes longer than anticipated but that it is less dangerous than feared. Or they may realize that they are not receiving the anticipated approval of supervisor and coworkers for riding their bikes to work. As a result, they may change their intentions with regard to future travel behavior.

In recent years, applications of the TPB in various behavioral domains have relied increasingly on structural equation modeling to test the model’s fit to the data. This requires transformation of the conceptual model shown in Figure 2 into a graphical model with latent and observed variables and analyzed as graphical input or syntax input by such programs as AMOS, LISREL, Mplus, EQS, R-lavaan or STATA (de Leeuw et al., 2015; Ho et al., 2013).

Empirical Evidence in Support of the TPB in General and in Predicting Individual Car Use

Besides its clear and parsimonious structure, the frequent use of the TPB as a theoretical framework for empirical research rests on its ability to predict behavioral intentions and behaviors across a variety of behavioral domains. Over 53 meta-analyses (e.g., Albarracín

¹ Note again that, theoretically, perceived behavioral control moderates the prediction of intentions from attitude and subjective norm, but in most applications, intentions are predicted from a linear combination of the three antecedent variables.

Table 1 Results of three meta-analyses on the relation between TPB variables and individual car use intention and behavior (Gardner & Abraham, 2008; Hoffmann et al., 2017; Lanzini & Khan, 2017)

	<i>Lanzini & Khan (2017)</i>				<i>Hoffman et al. (2017)</i>				<i>Gardner & Abrahams (2008)</i>

Note. *k* = number of pooled studies, *N* = pooled sample size, *r* + = pooled correlation between car use and psychological construct, 95% *CI* = 95% confidence interval

et al., 2001; Armitage & Conner, 2001; Haus et al., 2013; Overstreet et al., 2013; Schwenk & Möser, 2009) have demonstrated that attitude, subjective norm, and PBC explain 30%–50% of the variance in intention and that intention and PBC explain 20%–40% of the variance in behavior (Armitage & Conner, 2001; Webb & Sheeran, 2006).

In the domain of travel-mode choice, three meta-analysis have been published on the prediction of individual car use intentions and behavior (Gardner & Abraham, 2008; Hoffmann et al., 2017; Lanzini & Khan, 2017). Table 1 summarizes the main results of these meta-analyses.

As proposed by the TPB, in all three meta-analyses behavioral intention and PBC both significantly and substantially predicted individual car use. Two of the three meta-analyses (Gardner & Abraham, 2008; Lanzini and Khan, 2017) also examined the relation between driving intention on one hand and attitude, subjective norm and PBC toward driving on the other. As expected, attitudes, subjective norm and PBC accurately predicted driving intentions. However, it is striking to note the considerable differences in the meta-analytically pooled correlation reported by the Lanzini and Khan (2017) versus Gardner and Abraham (2008) and Hoffmann et al. (2017) meta-analyses: Whereas Lanzini and Khan (2017) reported an average correlation of $r + = 0.83$ between pooled car use intention reported car use, in the other two meta-analyses, the correlations were $r + = 0.53$ and $r + = 0.50$. Because the reported confidence intervals do not cover the large differences, they cannot be attributed to chance. The results reported by Lanzini and Khan (2017) seem to be based on a systematically different data set than the results of the two other two meta-analyses, which were quite similar.

As noted, in the TPB, behavioral, normative and control beliefs not only provide the bases for attitudes, subjective norms, and perceptions of behavioral control, they are also the central targets of effective interventions designed to change behavior. Despite the central role ascribed to beliefs in the TPB, relatively few TPB studies have examined these beliefs (Steinmetz et al., 2016). As a consequence, no meta-analyses on the association between the three belief types and attitude, subjective norm, and PBC are available. We can therefore only report the results of individual studies. In the domain of travel-mode choice, Bamberg and Schmidt (1992, 1998) conducted two of the few studies that systematically analyzed the role of beliefs in individual travel mode choice. For this purpose, Bamberg and Schmidt (1992) asked student to evaluate the importance and probability of ten behavioral beliefs related to different travel modes, such as quick, comfortable, without stress, and cheap. Simultaneously they asked how strongly important reference persons like friends, parents, or professors support the use of the car, bike and public transit for university trips and how motivated participants were to comply with these expectations. Additionally, important control beliefs, including availability of a car, bike, or public transport services, public transport knowledge, and perceived quality of public transport connection were assessed. A composite measure of 10 behavioral beliefs related to car use for university trips correlated $r = 0.75$ with attitude toward this behavior. Similarly, a composite measure of normative beliefs correlated $r = 0.72$ with the subjective norm toward car use, and a composite measures of control beliefs correlated $r = 0.85$ with perceived behavioral control over car use. For bike use the correlation between behavioral beliefs and attitude was $r = 0.69$, for normative beliefs and subjective norm $r = 0.74$, and for control beliefs and PBC $r = 0.74$. In the second study, Bamberg and Schmidt (1998) replicated these results using a much larger sample.

In a study on university employees' travel-mode choices for commuting, Mann and Abrahams (2012) also analyzed the relation between beliefs and attitude, subjective norm, and PBC. They found that five behavioral beliefs predicted 49% of the variance in attitudes toward car use for commuting, two normative beliefs accounted for 22% of the variance in subjective norms, and two control beliefs explained 6% of the variance in PBC. Similar results were obtained with respect to using public transit for commuting.

Using the TPB for Designing and Evaluating Behavioral Change Interventions

As stated in the introduction, one main reason for transport science's interest in better understanding of individual travel-mode choice is growing societal pressure to reduce the negative environmental impacts of motorized transport, especially private car use.

Table 2 Results of TPB interventions (Steinmetz et al., 2016)

	<i>k</i> (ES)	<i>N</i>	δ	95% CI	
Behavioral beliefs	11 (14)	2,902	0.39	−0.08	0.86
Normative beliefs	12 (17)	3,962	0.54*	0.05	1.03
Control beliefs	6 (6)	1,053	0.68*	0.00	1.36
Attitude	70 (101)	21,374	0.24*	0.15	0.34
Subjective norm	61 (85)	15,711	0.14*	0.08	0.19
PBC	80 (113)	24,897	0.26*	0.16	0.35
Intention	72 (108)	22,030	0.34*	0.24	0.45
Behavior	40 (51)	9,395	0.50*	0.24	0.75

Notes. *k* = number of studies; ES = number of effect sizes; *N* = sample size; δ = weighted average effect size; 95% CI = confidence interval.

Because in liberal societies using coercive measures is associated with high political costs, governments and local authorities are interested in developing effective interventions aimed at motivating individuals to voluntarily reduce reliance on their cars and adopt more environmentally friendly means of transportation such as walking, cycling or use of public transportation. Thus, from an applied perspective, the ultimate test of the TPB's usefulness consists in its ability to guide the development of effective behavior-change interventions, or more precisely, interventions that motivate participants to voluntarily reduce their car use. This is described in more detail in Fishbein and Ajzen (2011) and in Ajzen and Schmidt, 2020.

Designing a behavioral change intervention is a time- and labor-intensive process. With the TPB as a conceptual framework, Steinmetz et al. (2016) described this process as follows: Investigators first establish whether individuals fail to perform the desired behavior (e.g., cycling to work on a regular basis) because they are not motivated to do so, because they are motivated but incapable of carrying out the behavior (e.g., distance is too great), or both. To produce an intention to perform the behavior, the intervention must be targeted at behavioral, normative, and control beliefs that ultimately determine the behavior of interest. Once this has been accomplished, it becomes necessary to ensure that the participants have the means to translate their newly formed intentions into action. Such an approach requires the intervention to be closely tailored to the appropriate phase of the process (i.e., motivation vs implementation), accompanied by intermediate measures of the TPB constructs and adaptation of the process as needed. For instance, when prior steps to change motivation were not successful, moving to implementational methods may not be effective. Rather, starting a second cycle of motivational interventions may be more appropriate. The development of such policy measures is not a part of the theory itself but requires formulation of action hypotheses (Chen, 2014) that connect the policy measures with changes in behavioral, normative and control beliefs (see Figure 2).

Evaluating the effects of a newly developed intervention, one perhaps designed to reduce car use, is also costly. Drawing firm causal inferences requires experimental designs with randomized control trials (randomized assignment to a control- and treatment groups, e.g., Angrist & Pischke, 2015; Shadish et al., 2002) or at least quasi-experimental designs that include a control group but without random assignment. As a consequence, compared with the large number of correlational studies that have focused on testing the TPB's ability to predict intentions and behavior, the number of studies using the TPB for systematically designing and evaluating a behavior-change intervention is still relatively small. Recently Steinmetz et al. (2016) provided a meta-analytic summary of the results of these studies. They only included studies that used strong experimental or quasi-experimental designs, that is, studies had to include at least one treatment and one control group. Moreover, the treatment group had to be submitted to one or more behavior change methods that aimed to change one or several of the TPB variables. They were able to identify 82 papers reporting results of 123 interventions that satisfied these two criteria. Due to the limited number of studies that included measures of beliefs, it was not possible to investigate whether the intervention had a significant effect on the targeted behavioral, normative, and control beliefs. Hence, the analysis focused on the effects of the interventions on attitude toward the behavior, subjective norm, PBC, intention, and behavior.

Table 2 presents the main meta-analytical results. On average, interventions were successful in changing TPB variables. Most effect sizes were significant (except for behavioral beliefs) but moderate in magnitude, ranging from 0.14 for subjective norm to 0.68 for control beliefs. Most importantly, the interventions were quite effective in changing intentions ($\delta = 0.34$) and the targeted behavior ($\delta = 0.50$).

The behavior-change methods that could be analyzed in isolation were increasing skills, motivation, persuasion, and planning. Increasing skills was most successful in changing attitudes ($\delta = 0.39$), but surprisingly less effective in changing PBC ($\delta = 0.18$). Persuasion had its largest effect on PBC ($\delta = 0.49$) and intention ($\delta = 0.35$) and motivation was most successful for intention ($\delta = 0.51$). Planning had weak effects on intention ($\delta = 0.10$) and, as the only method, on subjective norm ($\delta = 0.16$). Furthermore, as can be seen in the last column, the assumption of homogeneity (*Q*) was falsified for all relationships, indicating that the effects of the interventions on the different TPB variables varied significantly across studies. Further research is needed to determine the factors responsible for the heterogeneity so that they can be taken into account in the development of policy measures.

In the domain of travel-mode choice the number of methodologically sound evaluation studies is small, and the number of TPB-based evaluation studies even smaller. Möser and Bamberg (2008) synthesized the results of 141 so-called "travel demand

management” interventions (TDM, [Kitamura et al., 1997](#)) from different narrative reviews published on the topic. Generally speaking, this kind of intervention can be characterized as information-centered approaches. [Möser and Bamberg \(2008\)](#) concluded that TDM interventions reduced by 7% the proportion of trips conducted by car (from 39% to 46%), a relatively small effect size that corresponded to a Cohen’s $d = 0.15$. The validity of this conclusion is, however, jeopardized by the weak methodological quality of the included studies, as all 141 studies used a one-group pre-test-post-test design. Two later meta-analyses have addressed this limitation. [Bamberg et al. \(2009\)](#), who assessed the effect of 15 behavioral interventions with experimental designs implemented in Japan, found an effect size of Cohen’s $d = 0.17$ as a result of such programs. Later, [Bamberg and Rees \(2017\)](#) meta-analyzed the results from eleven transport interventions with quasi-experimental and experimental designs, ten of which were conducted in the United Kingdom and one in Germany. Across the studies analyzed, an effect size of Cohen’s $d = 0.12$ was found, which corresponded to a reduction of approximately 5% in the car modal split share.

The above cited research by [Bamberg and Schmidt \(1998\)](#) is one of the rare examples of theory-based evaluation studies in the domain of travel-mode choice. It used the TPB as a theoretical framework for analyzing the effect of a “semester-ticket,” which consisted of the introduction in 1993 of a low-cost permanent regional public transport ticket for 30,000 students. The evaluation study assessed all TPB constructs before and after the introduction of the semester ticket. Results showed a significant increase in the beliefs “cheap” and “knowledge of time tables,” which was reflected in significantly higher means of the TPB constructs attitude, subjective norm, PBC, and intention. Actual use of public transport for university trips increased from 15.7% before introduction of the semester ticket to 30.6% after its introduction. However, a methodological weakness of this study is the problematic simple pre-test post-test design, which does not allow firm causal inferences concerning the intervention effect (see [Heath & Gifford, 2002](#), for a similar study with similar results). A later analysis based on data from all universities that had adopted the semester ticket by the year 2000 showed that, on average, private car use declined by 25%, which can be seen as another confirmation of the effect, this time based on the behavior of 1.6 million students.

Extending the TPB

Misunderstanding the TPB’s reasoned action assumption ([Fishbein & Ajzen, 2011](#)) to mean that in this framework people are assumed to be rational utility maximizers ([Bamberg & Schmidt, 1998](#); [Opp, 2019](#)), investigators have criticized the theory for underestimating the impact that moral beliefs and norms may have on people’s travel-mode choices. To remedy this situation, researchers have distinguished between subjective and moral norms (e.g., [Parker et al., 1995](#)) and have assumed that, in the context of climate change, moral norms may be an additional predictor of people’s intentions to drive their cars rather than use more environmentally friendly modes of transportation. For example, [Abrahamse et al., 2009](#) found that the TPB constructs were more powerful than moral norms in explaining current car use for commuting but that moral consideration were more powerful predictors than the TPB constructs for intentions to reduce car use in the future. In their meta-analysis, [Hoffmann et al. \(2017\)](#) reported a pooled correlation of $r = -0.35$ between perceived personal obligation of not driving (moral norm) and self-reported driving, for the same association [Gardner and Abraham \(2008\)](#) a pooled correlation of $r = -.41$, and [Lanzini and Khan \(2017\)](#) a pooled correlation of $r = -0.26$. Based on these results there is a growing consensus within the research community to view moral norms as an additional travel-mode-choice predictor, especially of the decision to use more environmentally friendly travel modes.

It has also been argued that the TBP does not adequately account for behaviors that may be regulated by automatic processes ([Triandis, 1977](#); but see [Ajzen & Dasgupta, 2015](#)). For instance, when behaviors are practiced in stable environments over time, they can be automatically initiated by environmental prompts with little or no conscious deliberation ([Strack & Deutsch, 2004](#)). Thus, since daily travel tends to occur in stable contexts, transport-mode choice may, over time, become less of a conscious choice and more of a habitual response executed with little reflection ([Gardner, 2009](#); [Gärling & Axhausen, 2003](#)). Habit was first introduced by [Triandis \(1977\)](#) as part of a behavioral model and it has been shown that the formation of habits may change the cognitive mechanisms underpinning travel-mode choice ([Aarts et al., 1998](#)). However, the use of past behavior frequency as an indicator of habit strength is problematic ([Fishbein & Ajzen, 2011](#)). For this reason, in their meta-analysis [Hoffmann et al. \(2017\)](#) included a summary of six studies using an independent measure of habit strength ([Verplanken & Orbell, 2003](#)) for predicting a person’s travel-mode choice. They found a pooled correlation of $r = 0.47$ between the habit measure and travel mode used. [Gardner and Abrahams \(2008\)](#) report a pooled correlation of $r = 0.50$, and [Lanzini and Khan \(2017\)](#) of $r = 0.42$. Thus, there is a growing consensus within the research community that a realistic model of travel-mode choice should also include an independent habit measure.

Conclusions

The research reviewed above provides strong support for the TPB as a useful theoretical framework for studying the role of psychological factors within the travel-mode choice process. Meta-analyses not only confirm the role of intention and PBC in predicting actual mode choice but also the role of attitude, subjective norm, and PBC as predictors of intentions. Still under-researched is the role of behavioral, normative, and control beliefs as determinants, respectively, of attitude, subjective norm, and PBC. In addition, we note two deficits in present research. First, investigators rarely use the framework provided by the TPB to derive systematic recommendations for public policy. Second, we have not seen any research on the effects of using laws or regulations to influence travel-mode choices. An example is provided by the introduction of free rides on public transportation for all employees of

the state of Hessia. It would be very useful to know how the effects of such an intervention, if any, can be explained by changes in the TPB constructs. Strong evidence is available for the effectiveness of TPB-guided interventions in other behavioral domains. Based on the evidence we reviewed in this chapter, we would recommend that researchers interested in understanding and influencing individual travel-mode choice also use the TPB as their conceptual framework for designing and evaluating an effective behavior-change intervention.

Introduction

Although people have traveled, traded, and shared goods and ideas for thousands of years, over the past 100 years there has been an almost unbroken rise in transport. The continuous mechanization of transport systems, the gradual shift from coal to oil, the improvements in engine propulsion technology and the associated reduction in mobility costs relative to incomes, have allowed people to travel at an unprecedented pace (**Fig. 1**).

Transport activity will continue to increase in the future as economic growth fuels transport demand and the availability of transport drives development. The majority of the world's population still does not have access to personal vehicles, and many do not have access to any form of motorized transport. However, this situation is rapidly changing. Industry analysts predict that there will be two billion motor vehicles on the roads by 2030, as private vehicle ownership spreads to the developing world ([Dargay et al., 2007](#); [Gross, 2016](#)). Both air passenger and air cargo traffic are resilient whereas freight transport has been growing even more rapidly than passenger transport and is expected to continue to do so in the future ([ICAO, 2017a](#)). Urban freight movement is dominated by trucks, while international freight is dominated by ocean shipping ([IEA, 2017a](#); [Mulholland et al., 2018](#); [UNCTAD, 2017](#)). **Fig. 2** summarizes these trends.

The paper is structured as follows: second and third sections provide a brief overview of the global energy end use in transport in general and the energy end use by transport mode; fourth section deals with the type of fuel used by each transport mode while fifth section discusses the transport greenhouse gas (GHG) emission trends; sixth section provides, first, an overview of the main policy approaches adopted by various regions around the world and, second, an overview of currently available best practices and promising developments for the near future to reduce energy-use in each transport mode.

Figure 3 Total transport energy consumption (exajoules) in OECD and non-OECD countries—(projection to 2040) (EIA, 2016).

Overview of Global Energy Use in Transport

According to the Energy Information Administration (EIA, 2016), the energy use of transport sectors has increased substantially in both OECD and non-OECD countries over the last decades (Fig. 3). In 2020, the OECD and non-OECD world transport energy use

Figure 4 Average annual growth in delivered transportation energy consumption by countries, 2012–40 (percent per year) and energy consumption added over the 2012–40 projection (EIA, 2016).

Figure 5 Transportation modes and energy (Samaras and Vouitsis, 2013).

are projected to be equal. The consumption in OECD countries remains relatively flat through the projection period because fuel efficiency improvements keep pace with increases in energy demand.

In non-OECD countries, the energy consumption in transport increased dramatically since 1990 (about 20 EJ) and is projected to reach 100 EJ in 2040. China's consumption of transport fuels is expected to increase on average by 2.7%/year from 2012 to 2040 whereas India also will experience substantial growth, adding eight EJ consumption over the period 2012–40 at an average annual increase of 4.4% (Fig. 4). The other economies of non-OECD also are expected to experience significant growth in transport energy demand from 2012 to 2040, adding 16 EJ consumption at an average annual increase of 3%.

Energy Consumption by Mode

The relationship between transport and energy is a direct one, but subject to different interpretations since it concerns different transport modes, each having a specific performance level. There is often a compromise between speed and energy consumption, related to the desired economic returns (Fig. 5).

Passengers and high-value goods can be transported by rapid but energy intensive modes because the time component of their mobility tends to have a high value. Economies of scale, mainly those achieved by maritime transport, are linked to low levels of energy consumption per unit of mass being transported, but at a lower speed. This fits relatively well with freight transport imperatives, particularly bulk. Comparatively, air freight has high energy consumption levels linked to highspeed services.

Furthermore, energy use in the transport sector has strong modal variations (Rodrigue et al., 2013):

Figure 6 Top: transport energy consumption by mode in OECD and non-OECD countries (2012 and 2040) (EIA, 2016). Bottom: passenger road transport split by vehicle type (2012 and 2040) (GEA, 2012).

Land Transport

Land transport (road, rail, pipelines) accounts for the great majority of energy consumption, using on average 75% of the total transport energy and will continue to weight around 70% up to 2040.

Road transport alone is consuming on average 96% of the total energy used in the land transport. In 2012, road transport accounted for 72% and 60% of the energy consumed in transport in OECD and non-OECD countries, respectively (Fig. 6, top). In OECD countries, road passenger vehicles (cars, light trucks, buses, two- and three-wheel vehicles) accounted for 73% and road freight vehicles for 27% of the land transport energy consumption (Fig. 6, bottom). In non-OECD countries, the corresponding shares were 79% and 21%. In the former, the passenger car dominated, accounting for more than 60% of the total road transport activity. In the latter, road passenger vehicles accounted for 23%, though two, three wheelers and buses also made significant contributions to passenger mobility (15%). Projections for the 2040 suggest that the percentage of energy consumed in road transport will be reduced in both OECD and non-OECD countries (to 60% and 48%, respectively) whereas the contribution of the passenger car in the total road transport activity will be further increased in both country clusters (EIA, 2016).

Rail transport which, on the basis of 1 kg of oil equivalent, is four times more efficient for passenger movement and twice as efficient for freight movement, consumes 2% of the energy used in OECD land transport and 8% of the energy used in non-OECD land transport. There is scope for further improving the energy and emissions performance of rail transport, but most technical measures are only presently cost-effective in new rolling stock (i.e., retrofitting outside of refresh cycles is usually uneconomic). Electric rail is typically 15%–40% more efficient than diesel rail, but only lines that run at least 5 - 10 trains per day are economically suited for electrification. Fig. 7 (top) compares the world railway energy fuel mix (1990 vs. 2015) and Fig. 7 (bottom) shows the sources from which railway-electricity is generated (1990 vs. 2015).

Air Transport

In 2012, the air transport of people and goods accounted for 10% and 12% of the energy consumed in transport in OECD and non-OECD countries, respectively and is expected to grow to 15% and 18%. Thus, in 2040, it will become the second biggest passenger mode after road transport (Fig. 6, top). Passenger air travel demand growth is expected to gain solid momentum in all regions, supported by the improvement in global economic conditions. Underpinned by these conditions that increase import and export orders, air cargo will also increase.

Maritime Transport

In 2012, energy consumption in maritime transport accounted for 17% and 12% of the energy consumed in transport in OECD and non-OECD countries, respectively and is expected to grow to 22% and 24% in 2040 (Fig. 6, top). Maritime transport is essential to

Figure 7 Top: world railway energy fuel mix (%) (1990 vs. 2015); bottom: world railway-electricity by source type (%) (1990 vs. 2015) (IEA, 2017b).

Figure 8 World transport sector delivered energy consumption by fuel type, 2010–40 (exajoules) (EIA, 2016).

the world's economy as over 90% of the world's trade is carried by sea and it is, by far, the most cost-effective way to move goods and raw materials around the world.

Fuel Type by Mode

Worldwide, petroleum and other liquid fuels are the dominant source of transport energy, although their share of total transport energy is projected to decline over the period 2012–40 (from 96% in 2012 to 88% in 2040) (EIA, 2016). Two fuels (motor gasoline (including ethanol blends) and diesel (including biodiesel blends) accounted for 77% of total delivered transport in 2012 and it is projected to account for 70% in 2040. Motor gasoline, which is used primarily for the movement of people remains the largest transport fuel, but its share of total transport energy consumption is expected to decline from 39% in 2012 to 33% in 2040. Diesel (including biodiesel) used primarily for the movement of goods, especially by trucks, shows the largest gain over the period 2012–40 (15 EJ) and jet fuel used in air transport gain more than 10 EJ.

Natural gas share will grow from 3% in 2012 to 11% in 2040 (EIA, 2016). This strong increase is mainly due to natural gas use by large trucks (from 1% in 2012 to 15% in 2040) (OIES, 2016). In addition, 50% of bus energy consumption is projected to be natural gas in 2040, as well as 17% of freight rail, 7% of light-duty vehicles, and 6% of domestic marine vessels. Residual fuel oil (RFO), which is used in marine transport will increase its share from 9% in 2012 to 11% in 2040. Electricity will remain a minor fuel for the world's transport energy use, although its importance in rail transport will remain high - particularly for passenger routes with high traffic volumes. The electricity share of total light-duty vehicle energy consumption grows to 1% in 2040, as new plug-in electric vehicles increasingly penetrate the total light-duty stock.

Figure 9 Global electric car sales and market share, 2013–18. (IEA, 2019). Note: the countries in this figure represent the top-ten countries. This ranking closely resembles the 10 leading countries worldwide in term of electric car sales; the only exception is Korea, with 33,000 electric car sales in 2018. Other includes Australia, Brazil, Chile, India, Japan, Korea, Malaysia, Mexico, New Zealand, South Africa, and Thailand. Europe includes Austria, Belgium, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Liechtenstein, Lithuania, Luxembourg, Malta, Netherlands,

Figure 10 Future global EV sales by scenario, 2018–30 (IEA, 2019). Note: the New Policies Scenario aims to illustrate the impact of announced policy ambitions; the EV30@30 Scenario takes into account the pledges of the Electric Vehicle Initiative's EV30@30 Campaign to reach a 30% market share for EVs in all modes except two-wheelers by 2030 (PLDVs = passenger light-duty vehicles; LCVs = light-commercial vehicles; BEV = battery electric vehicle; PHEV = plug-in hybrid vehicle).

However, EIA' projections for electricity in the light duty vehicle fleets appear rather conservative as indicated in IEA's recent market analysis (Fig. 9) (IEA, 2019). Global electric car sales were close to 2 million in 2018, after having reached the 1 million mark in 2017. This is related with the continuing fall of diesel models' sales as the fuel type falls out of favor with customers. Furthermore, IEA's projections indicate a rising tide of electric vehicles (Fig. 10) (IEA, 2019).

GHGs Emissions

Globally, CO₂ accounts for 95% of transportation GHGs. HFCs, which are used in automobile, aircrafts, truck, and rail air conditioning and refrigeration systems, account for another 3% of transport GHG emissions. N₂O and CH₄, which are both emitted as byproducts of combustion, account for the remainder of the transport GHG emissions inventory. Water emissions at the Earth's surface have no climate effect. If released at cruise altitude by commercial aircraft, however, water vapor emissions can be more significant (Samaras and Vouitsis, 2013).

According to IEA (IEA, 2018), the global transport sector produced 6.62 GtCO₂ emissions in 2016, and it was the second larger emitter after the power generation sector (13.41 GtCO₂), contributing about 21% of the global GHG emissions (Fig. 11, top). The Americas and Asia contribute 38% and 37%, respectively, Europe contributes 19% and Africa/Oceania 7%. North America and Oceania have disproportionately high emissions relative to their population (Fig. 11, bottom).

Figure 11 Top: CO₂ emissions by sector for selected regions, 2016 (IEA, 2018). Left: CO₂ emissions of transport per capita for selected regions, 2000–14 (WEC, 2014).

Figure 12 Global CO₂ emissions from aviation under various scenarios, 1990–2050.

Road Transport

Within road transport, automobiles and light trucks produce well over 60% of emissions, but in low- and middle-income developing countries, freight trucks (and in some cases even buses) consume more fuel and emit more CO₂ than the automobiles and light trucks (Samaras and Vouitsis, 2013). Although there is yet no global-gridded rail inventory available, this sector is certainly the lowest CO₂ emitter (in terms of “tailpipe” emissions at least) because it has been to a large extent electrified. Available studies show that rail emissions make up only 1%–3% of the total transport emissions (IEA, 2017b).

Air Transport

Although the average fuel burn of new aircraft fell approximately 45% from 1968 to 2014 (Kharina and Rutherford, 2015), the total amount of fuel burned has still increased due to even higher growth in air traffic. According to a recent study by the International Council on Clean Transportation (Graver et al., 2019), worldwide aviation CO₂ emissions increased by 32% from 2013 to 2018. The total increase over these five years was equivalent to building about 50 coal-fired power plants, according to the study. The implied annual compound growth rate of emissions, 5.7%, is 70% higher than those used to develop International Civil Aviation Organization’s (ICAO) projections that CO₂ emissions from international aviation will triple under business as usual scenario by 2050. Given the sustained growth of the air transport industry, aircraft emissions are expected to increase in the short-term future.

Figure 13 Global CO₂ emission projections for international maritime transport (ENVI, 2015).

Figure 14 International aviation and maritime transport's share of global GHG emissions under the Representative Concentration Pathway (RCP) 2.6 pathway (ENVI, 2015).

Although technological and operational improvements have a potential to reduce CO₂ emissions by 33% in 2050 compared to the baseline, CO₂ emissions are still projected to be seven times higher in 2050 than in 1990; without the improvements, projections are ten times above 1990 levels in 2050 (Fig. 12).

Maritime Transport

Estimates for the global CO₂ emissions for maritime transport differ substantially depending on the approach (bunker fuel statistics or activity-based figures). Fig. 13 depicts International Maritime Organization (IMO)'s projections under three different scenarios as well as the effect of the most ambitious mitigation option on the reference scenario (ENVI, 2015). As in the case of air transport, the technological and operational improvements reduce CO₂ emissions in 2050 by 33%. Other studies show a similar range of baseline emissions and upper/lower bounds. Despite this, they are still projected to increase by a factor of almost four compared to 1990. Without these improvements, the growth would be sixfold.

It is worth mentioning that initiatives and actions taken by ICAO and IMO to address GHG emissions started late and so far, have been insufficient from an environmental perspective. If the ambition of the two sectors continues to fall behind efforts in other sectors and if action to combat climate change is further postponed, their CO₂ emission shares in global CO₂ emissions may rise substantially to 22% for international aviation and 17% for maritime transport by 2050, or almost 40% of global CO₂ emissions if both sectors are considered together (Fig. 14).

Reducing Transport Energy Consumption

Regulations

Land Transport

Due to various historical, cultural, and political reasons, different countries and regions have chosen to adopt different fuel economy (FE) or emission standards (ES). These standards differ in stringency, by their apparent forms and structures and by how the vehicle

Table 1 Overview of regulation specifications for passenger cars (Yang and Bandivadeka, 2017)

Country/region	Regulated metric	Unadjusted Fleet target/measure (target year)	Form of target curve	Test cycle
EU-28	CO ₂	95 gCO ₂ /km (2021)	Weight-based corporate average ¹	NEDC and WLTC ^a
USA	Fuel economy/GHG	55.2 mpg and 147 gCO ₂ /mi (2025)	Footprint (size)-based corporate average	US combined ^b
China	Fuel consumption	5 L/100 km (2020)	Weight-class based corporate average	NEDC
India	CO ₂	113 g/km (2022)	Weight-based corporate average	NEDC
Japan	Fuel economy	20.3 km/L (2020)	Weight-class based corporate average	JC08 ^c
Saudi Arabia	Fuel economy	17 km/L (2020)	Footprint-based corporate average	US combined
Canada	GHG	217 gCO ₂ /mi ^d (2016) N/A ^e (2025)	Footprint-based corporate average	US combined
Mexico	Fuel economy/GHG	39.3 mpg or 140 g/km (2020)	Footprint-based corporate average	US combined
South Korea	Fuel economy/GHG	24 km/L or 97 gCO ₂ /km (2020)	Footprint-based corporate average	US combined

^aNEDC: New European Driving Cycle, WLTC: Worldwide harmonized Light vehicles Test Cycles.

^bFTP-75 cycle and Highway Fuel Economy Test cycle.

^cJapanese JC08 Cycle.

^dIn April 2010, Canada announced a target for its LDV fleet of 246 g/mi for model year 2016.

^eCanada follows the US standards in the proposal, but the final target value would be based on the projected fleet footprints.

**Figure 15** Historical fleet CO₂ emissions performance and current standards (gCO₂/km normalized to NEDC) for passenger cars (Yang and Bandivadeka, 2017).

FE or GHG emission levels are measured—that is, by testing methods. They also differ by implementation requirements, such as mandatory versus voluntary approaches. Thus, policymakers are faced with many choices when they decide GHG emission/fuel economy standards. **Table 1** summarizes the basic policy approaches adopted by various regions for passenger cars and it is an illustrative example of the above-mentioned differences on interpretation and approach. **Fig. 15** compares country standards for passenger vehicles in terms of grams of CO₂-equivalent/km adjusted to the European NEDC test cycle.

The EU-28 has the lowest fleet average target of 95 gCO₂/km by 2021. However, South Korea will match, if not exceed, the EU-28 with a fleet target of 97 gCO₂/km in 2020. With its high hybrid percentage, Japan already reached its 2015 target of 142 g/km in 2011 and 2020 target of 122 g/km in 2013. If Japan continues to reduce CO₂ emissions at the same rate as from 2010 to 2014, Japan's passenger vehicle fleet would achieve 82 g/km in 2020, far below the targets set by other countries. The United States and Canada, long laggard in regulating fuel economy, have evolved into leaders. As the first country with 2025 targets, the US example has encouraged other countries to consider enacting similarly long-term standards. The United States is expected to achieve 45% GHG emission reduction from 2010 to 2025. China announced a fleet average fuel consumption of 4L/100 km by 2025, which would be among the lowest target levels once it is supported by detailed standards. However, a gap between official test results and real-world performance of new cars' CO₂ emissions has grown alarmingly, it dilutes the fuel economy standards and makes real-world fuel consumption an issue that needs to be addressed (Yang and Bandivadeka, 2017).

Air and Maritime Transport

Globally, the majority of GHG emissions from the air and maritime transport are still unregulated. While some countries have enacted domestic policies, most have not. Independently, New Zealand, Australia, and the EU-28 have already taken steps to include aviation in their domestic GHG cap-and-trade programs. The EU-28 Emissions Trading System (EU ETS) is the cornerstone of the EU's policy to reduce, in a cost-effective manner, GHG emissions from aviation among others (EC, 2013). The ETS is a cap-and-trade system, which sets a limit on the number of emissions allowances issued, and thereby constrains the total amount of emissions of the sectors covered by the system. The gradually more limited supply of allowances drives operators in need of additional allowances to

Table 2 Practical limit to energy efficiency improvements by reducing road load

<i>Transport mode</i>	<i>Practical limit (%)</i>
Cars	91
Trucks	54
Rail	57
Air	46
Maritime	63

buy them on the market from other sectors in the system—hence cap-and-trade system. Between 2013 and 2020, an estimated net saving of 193.4 MtCO₂ will be achieved by air transport via the EU ETS through funding of emissions reduction in other sectors (EEA, 2019).

As mentioned above, addressing GHG emissions from international aviation and marine shipping is especially challenging, because they are produced along routes where no single nation has regulatory authority. Unlike other sources of GHG emissions, international emissions from aviation and marine transport are specifically excluded from developed countries' national targets. Instead, limitations or reductions in emissions from these transport modes could be achieved by working through ICAO and IMO. In response to this mandate, both organizations have initiated activities aimed at addressing emissions from their respective sectors, but thus far nothing substantial has been achieved. In 2017, the ICAO Council adopted a new aircraft CO₂ emissions standard which presents the world's first global design certification standard governing CO₂ emissions for any industry sector (ICAO, 2017b). The standard will apply to new aircraft type designs from 2020, and to aircraft type designs already in-production as of 2023. Those in-production aircraft which by 2028 do not meet the standard will no longer be able to be produced unless their designs are sufficiently modified. IMO's "Initial Strategy" (IMO, 2018) envisages for the first time a strategy which aims to reduce the total annual GHG emissions by at least 50% by 2050 compared to 2008.

Technology

Technologically, the reduction of the energy used in transport can be accomplished by two ways: either by engine efficiency and transmission improvements or by reducing road load, that is, the mass of the vehicles and the resistances to motion. Table 2 summarizes the practical limit to energy efficiency improvements for each transport mode (Cullen et al., 2007). The largest savings may occur in passenger cars (91%), where reducing the mass of the car and the rolling resistance are important. Cars are also less optimized because of the diversity of models and the need to compromise efficiency to satisfy the fashion element of car design. Airplane, where the weight of any additional fuel must be supported by the lift force generated by the engine thrust and wings, is the most optimized of the systems with only 46% practical energy savings available. Light weighting strategies for ships and trains are limited because the transported goods make up a large proportion of the total vehicle mass (typically 60% in trucks versus 5%–10% in cars).

More specifically, the technology measures to improve energy efficiency, include:

Road Transport

Road transport is dominated by the internal combustion engine and the technology measures to improve energy efficiency, include (Samaras and Voutsis, 2013):

- Aggressive electrification of the car fleet (hybrid, battery electric and fuel cell vehicles);
- Significant downsizing, including a change of the engine architecture to the next smaller engine family plus turbocharging;
- Stratified part-load operation with key enabler the spray guided stratified combustion, with its best possible fuel economy improvement versus homogeneous operation;
- Natural gas, synthetic diesel, and biofuels;
- Friction reduction and thermal management, as well as high compression ratio enabled by homogeneous direct injection;
- Increasing vehicle loading rates in freight transport.

Air Transport

The need for air transport to be more fuel efficient will be driven in the coming years both by fuel prices and environmental taxes or caps. Past trends in fuel efficiency vary considerably depending on the measure and the period chosen (Singh and Sharma, 2015). For the period 1959–95, the reduction in energy intensity was mainly improvement in engine efficiency (57%), aerodynamic efficiency (22%), aircraft capacity (17%), and other changes such as increased aircraft size (4%). For the period 1970–2006, improvements were mainly due to improvements in load factor (20%), aircraft size (26%), and finally technical and operational improvements to the fleet (24%). Fig. 16 summarizes the modeled trend in average new aircraft fuel burn from 1960 to 2014 on ICAO's Metric Value (green line) and a fuel/passenger-km metric (blue line), normalized to 1968. Beyond technological advances, the fuel efficiency of air transport can be improved by operation measures, and management of air traffic.

Figure 16 Average fuel burn for new commercial jet aircraft, 1960–2014 (1968 = 100) (Kharina and Rutherford, 2015). ICAO's MV is a proxy of cruise fuel efficiency that is calculated as function of an aircraft's specific air range (SAR) and Reference Geometric Factor (RGF), which is a close approximation of the pressurized floor area of the aircraft.

Maritime Transport

Low speed two-stroke turbocharged diesel engines are the most commonly used for maritime propulsion today. These engines are the most efficient, exhibiting 50% efficiency. Technological measures for increased efficiency may be either those which can be introduced only at the design/building stage or those which can be retrofitted to existing ships (IMO, 2014). A combination of technical measures could reduce total energy use by 4%–20% in older ships and 5%–30% in new ships by applying state-of-the-art knowledge, such as hull and propeller design and maintenance (GEA, 2012). Operational measures, such as speed reduction, offer a large and near-term mitigation option, while improving the energy efficiency of new ships and switching to alternative fuels provide longer-term potential. Reducing the speed at which a ship operates brings significant benefits in terms of lower energy use. For example, cutting a ship's speed from 26 to 23 knots can yield a 30% fuel saving.

Behavioral Changes

The main target is to reduce congestion through encouraging behavioral change towards more sustainable modes of transport. Increasing occupancy rates in passenger transport is an attractive strategy because it can be achieved with the existing public transport or private vehicle stock. Although very difficult to implement in private transport, ride sharing applications would reduce the numbers of vehicles on the road and vehicle-km driven; when differences in occupancy rates are taken into account, public transport modes are usually much more energy efficient than car travel, as can be seen most clearly by comparing bus and car travel, both of which use petroleum fuels (EEA, 2015). Other actions for travel behavior change include, among others, parking policy, limited traffic zones, traffic light timing, job ticket, upgrade of sidewalk infrastructure, development of cycling infrastructure.

Furthermore, it is expected that Cooperative Intelligent Transport Systems (C-ITS) and Connected and Automated Vehicles (C&AV) will have a very important impact on driver behavior. The current phase of development in C-ITS and C&AV has already been considered the biggest innovation in automotive industries since the invention of the car itself. It could help to significantly reduce road fatalities from road accidents. New transport services may also emerge, especially when vehicles are provided with connectivity in addition to automation (e.g., traffic safety related warnings, traffic management, car sharing, new possibilities for elderly or impaired people). Finally, the deployment of driverless mobility—when fully integrated in the whole transport system and accompanied by the right support measures and synergies between driverless mobility and decarbonization measures—is expected to contribute significantly to achieving key societal objectives (EC, 2018)

Summary and Conclusions

Given the huge demand for both vehicle ownership and transport in the non-OECD countries, a strong case can be made for a continuation of high growth in transport energy demand. Current trends in urban developments are a reason of concern in terms of climate, because they are allowing private cars to gain dominance over public transport or nonmotorized travel. No matter if the mode share of automobiles is low, as in emerging economies, or very high, as in the developed world, the trend is clear: people are buying more cars every day and once they have them, they use them. Consequently, the energy use (and GHG emissions) from urban passenger transport continues to increase.

Rail transport, which is the most efficient passenger mode, should be considered as an effective way to make transport more carbon efficient. Air transport has improved its fuel efficiency significantly over the years and technology developments might offer a further

improvement in the future. However, since aviation's growth rate is projected to be high, such improvements may not be enough to keep energy use from increasing. The available maritime transport technology can cost-effectively achieve high efficiency gains.

Achieving sustainability goals in transport within the limited time frame of a few decades requires transformative actions and political commitment from the local communities to the supranational and global level. These include:

Road Transport

- Full electrification of passenger cars—improvement of the range of electric vehicles will be a key success factor the coming years; it will also be important to develop short range, up to 150 km, low cost electric vehicles which will be very effective in city environments; expansion of electrification to urban buses and to heavy duty sector;
- Improving the performance of next generation fuel cell electric vehicles (FCEV);
- Renewable fuels and further energy efficiency improved mono-fuel natural gas engines and direct injection.

Rail Transport

- Full electrification;
- Lighter materials in vehicles and wider use of energy recuperation devices (e.g., regenerative braking or energy storage technologies).

Air Transport

- Innovative aircraft technology and improvements of existing technologies (e.g., better aerodynamics, jet engine efficiency);
- Development and application of sustainable bio-kerosene sourcing production and distribution;
- Hydrogen-powered fuel cells;
- Improving air traffic management technologies, procedures and systems.

Maritime Transport

- Optimization of conventional ship engines, including fuel flexibility, new materials, lifetime performance and near zero emissions engines;
- Development of standardization in order to ease certification of such engines;
- Market based measures.

Biography

Dr Zissis Samaras is a full professor and director of the Lab of Applied Thermodynamics (LAT), Department of Mechanical Engineering, Aristotle University, Thessaloniki, Greece. His research work deals primarily with engine and vehicle emissions testing and modeling and he has carried out a wide range of projects on modeling emissions from internal combustion engines. He has provided expert advice to several organizations and private sector customers, including the European Commission, the European Environment Agency, the World Bank the Greek Ministry of Environment, Rhône-Poulenc, ACEA, Concawe, Toyota Motor Europe. He is elected academic member and vice chairman of the European Road Transport Research Advisory Council (ERTRAC) on "Energy, Environment and Resources." He is the author of more than 160 papers in peer-reviewed journals and seven book chapters, which received according to Scopus more than 4500 citations in peer reviewed articles, reviews, and technical notes.

Dr Ilias Vouitsis is a senior researcher at the Lab of Applied Thermodynamics (LAT), Department of Mechanical Engineering, Aristotle University, Thessaloniki, Greece. His research interests lie in the areas of energy conversion and exhaust emissions with emphasis on particle emissions. He has experience in development of emission factors for light duty, heavy duty vehicles and motorcycles. He has been actively involved in several major research projects funded by both the European Union and the industry on emission related legislation as well as on automotive product development. He has been the author and coauthor of over 30 scientific and technical papers and of three book chapters.

Limited Mobility

This article focuses on the factors that affect the choice of transport mode by people who have limited mobility, and the barriers that prevent them from using some modes as much as other people. There are several ways in which mobility can be limited, as [Table 1](#) shows.

Limitations on mobility can be permanent or temporary. Any traveler can have a temporary mobility limitation such as heavy baggage. Young children have temporary limitations on their mobility because they cannot walk as far or as fast as an adult and do not have the mental capacity or knowledge to use public transport alone but will acquire these capabilities as they grow up. Escorting young children can place limitations on the mobility of adults.

Elderly people may lose their ability to walk quickly, climb stairs or drive safely because of the gradual deterioration in their faculties. This group overlaps with people with disabilities because many disabilities occur in older age.

[Table 2](#) shows the effects of having a disability on mobility. The range of disabilities indicated in the table are the categories of disability used in surveys carried out for the British Government ([Office for National Statistics, 2017](#)). In Britain, a disability is defined as a health condition expected to last more than 12 months which reduces the ability to carry out day-to-day activities ([Office for Disability Issues, 2011a](#)). On average, the population makes 1012 trips a year. Those with a disability make 853 trips on average, while people without a disability make 1055. There is a range across the various types of disability from 594 for people with social/behavioral conditions to 787 for people with stamina, breathing and fatigue conditions and 930 for other disabilities. This illustrates that nonvisible disabilities may affect mobility. For more information about travel by disabled people see [Article 10750](#) and about travel by older people see [Articles 10163](#) and [10614](#).

There are similar definitions of disability related to mobility used in many countries. For example, in the United States, the National Household Travel Survey asks respondents if they have "a temporary or permanent condition or handicap that makes it difficult to travel outside of the home" ([Federal Highway Administration, 2020](#)).

This article focuses on people with permanent mobility limitations because temporary mobility limitations are unlikely to have an adverse long-term effect on people's lives.

The structure of this article is as follows: the next section describes the modes of transport used by disabled and elderly people. Then the barriers that prevent them from using some modes as much as others are discussed, followed by a brief discussion about interventions that may increase travel by those modes.

Transport Modes Used by Disabled and Elderly People

[Table 3](#) shows the trips made by each mode by disabled and nondisabled people in England. The most popular mode for both groups is the car or van. Combining drivers and passengers, disabled people make 61.5% of their trips by this mode compared with 62.4% by others. More disabled people are car passengers than nondisabled people. Despite this, many more car trips by disabled people are as drivers than as passengers. Combining the public transport modal shares of bus, rail, and taxi, there is little difference between the two groups: 9.9% of trips compared to 10.2%. Disabled people use bus and taxi more than other people, whereas nondisabled people use rail more, particularly the London Underground, a metro system. This difference may reflect the fact that nondisabled people are more likely to be employed and use rail to travel to work. Turning to active travel, disabled people make fewer walking trips than nondisabled people, but walk a greater proportion of their trips. They cycle less than nondisabled people.

[Table 4](#) shows equivalent figures for the United States, for trips by workers and nonworkers up to the age of 64 years. Personal vehicle (car, van, or similar) is the most popular mode for both groups, with more nondisabled people traveling by car, and disabled

people more likely to be car passengers and less likely to be drivers than nondisabled people. Disabled people use public transport (local transit) more than nondisabled people. Walking is more popular for disabled people than those without a disability.

A similar picture emerges in the United States for older people, as **Table 5** shows. Car is still the dominant mode with more trips as a car driver than as a car passenger, for disabled people, despite their age and disabilities. Disabled people use local transit and paratransit more than nondisabled people. However, older disabled people walk less than nondisabled people.

Spatial factors such as density and distance from the city center can affect modal choice. **Table 6** shows the percentage of trips by each mode by disabled and nondisabled people in New York in three different areas: the New York Metropolitan Transportation Council (NYMTC) area, which is an area with high densities and high level of provision of public transport, the rest of New York state, which is less dense, but is denser, on average than the rest of the United States, which is the third area shown. The general picture is similar across the three areas, but with higher car use outside the NYMTC area. In all cases, including the NYMTC area, more trips by disabled people in privately owned vehicles are as drivers rather than passengers. One difference between the three areas is that disabled people walk less than other people in the rest of New York State area.

Table 4 Modal share by worker and disability status (age 18-64 years) in the United States in 2017

Turning to older people, **Table 7** shows the modal shares for people aged 50-59 years, 60-69 years, and aged 70 + years. The number of trips made declines with increasing age, as does the volume of car driving. The number of trips as a car passenger increases after the age of 60 years and stays fairly constant after that in terms of the number of trips but increases in terms of modal share. Even over the age of 70 years, more than twice as many car trips are as a driver than as a passenger. The decline in car use is partly compensated for by an increase in bus usage with age, but rail use declines. This may be because of the changes in the nature of trips by older people and the reduction in the distance traveled with increasing age (Mackett, 2017). Walking increases slightly after the age of 60 but declines later in terms of trips, but increases in terms of modal share. The low levels of cycling decline with age.

Table 8 shows equivalent figures for the United States. The shift from being a car driver to being a car passenger with increasing age can be seen, but even over the age of 75 years, car driving is still the dominant mode. The other modes show little change over time because of the dominance of car use.

Barriers to Transport Modes Used by Disabled and Elderly People

Evidence discussed above showed that disabled and older people travel less than other people and use different modes of travel. Nondisabled people may also not use some modes as much as they would like for reasons such as cost or lack of availability. As **Table 9**

Table 7 Trips per person per year by each mode in England by people aged 50 years and older in 2018

	<i>Ages 50-59</i>		<i>Ages 60-69</i>		<i>Ages 70+</i>

Source: *Office for Disability Issues (2011b)*.

shows, this is the case. For all modes, more disabled people use the modes less than they would like than non-disabled people. The motor vehicle is the mode that the greatest number of disabled people cannot use. It is also the mode for which the difference between disabled and nondisabled people is greatest at 13%. Local buses and long-distance trains are the two modes after motor vehicles that most disabled people use less than they would like. Taxis are the mode that the fewest disabled people are unable to use.

Table 10 shows the barriers to use of motor vehicles for disabled and nondisabled people. More disabled people than nondisabled people face at least one barrier to using a motor vehicle. For both groups, cost is the top factor, deterring about half of each group. The next two barriers for disabled people are having a health condition, illness, or impairment and having a disability. Some long-term health conditions affect the use of a motor vehicle because it prevents them from obtaining a driving license. The only other issue that affects disabled people more than nondisabled is parking problems, which may reflect the difficulties that wheelchair users can have finding a suitable parking space.

Table 11 shows the barriers to using buses and taxis. For each of the modes shown, more disabled people than nondisabled people face barriers to using the mode. Many people cited having a health condition, illness, or impairment or a disability as a barrier, more so for buses than for taxis. This may be because taxis carry passengers from door-to-door, avoiding the need to walk along the street, which may be a barrier to some people. This is confirmed by the relatively large numbers of people who cited getting

Source: *Office for Disability Issues (2011b)*.

to or from the stop or station as a barrier for the bus compared to the numbers mentioning this for taxi. Similar numbers of disabled people mentioned the difficulty of getting in or out of the transport as a barrier to use of the mode. The only other barrier which was cited by many more disabled people than nondisabled people was anxiety/lack of confidence, implying that there are psychological barriers to using these modes. There is evidence of these for people with mental health conditions in [Mackett \(2019\)](#). A factor for many people was cost, especially for taxis. This was a barrier for more nondisabled people than disabled, either because some disabled people are provided with cheap or free travel for these modes or because other factors were such a deterrent to using the modes that they did not consider the cost of using them.

Moving to rail, [Table 12](#) shows the barriers to traveling by rail for disabled people. The key barriers mentioned as well as having a disability, are accessing the train both getting to and from the station and getting on and off the train, and anxiety/lack of confidence.

The possible causes of the anxieties traveling on public transport are illustrated by the figures in [Table 13](#), which shows the percentage of people living in London identifying barriers to greater use of public transport. Barriers cited by more disabled people than non-disabled people were fear of crime both on the bus or train or traveling to it, fear of terrorist attacks, the risk of accidents and graffiti. The much higher figures for the fear of crime in [Table 13](#) compared to those in [Tables 11 and 12](#) probably reflects the fact that [Table 13](#) is for London where street crime is much higher than in other parts of the country.

Interventions to Increase Modal Usage by Older and Disabled People

It has been shown that older and disabled people travel less by most modes than other people. Car is the mode that they use most, but less than other people. The development of fully autonomous vehicles which do not require the user to perform any control functions should enable older and disabled people to travel by car as much as they wish, providing that they can afford to do so. For more information about autonomous vehicles see Articles 10093 and 10400.

One area that prevents disabled and older people from using some public transport modes is difficulty accessing the vehicles. This requires better design of both the vehicles and the street environment to facilitate access. The design process should involve disabled and older people. Another barrier to use of some modes was anxiety/lack of confidence. One way to address this is to provide more staff who have been trained to offer appropriate assistance. Clear information about wayfinding, purchasing tickets, and obtaining help are all useful in providing reassurance.

Conclusions

This article has shown that people with long-term mobility limitations travel less than others and they use a different mix of modes. In Britain and the United States, most of their trips, like the rest of the population, is by car, but they are more likely to be car passengers than nondisabled people. Disabled people tend to use buses and taxis more but are less likely to travel by train than

nondisabled people. The reasons for the lower levels of use of some modes by disabled people than the rest of the population include difficulties accessing buses and trains and anxiety and lack of confidence about using them. For car driving, a major factor may be that some disabled and older people are not able to hold a driving license.

Biography

Roger Mackett is Emeritus Professor of Transport Studies at University College London. He has researched into various aspects of transport policy including the barriers to access for older and disabled people, the use of cars for short trips and the effects of car use on children's lives. He is a member of the Disabled Persons' Transport Advisory Committee (DPTAC) and the Standing Committee on Accessible Transportation and Mobility of the US Transportation Research Board (TRB).

Introduction

Some form of paid employment is a necessary part of most people's lives, and travel to and from work can form a significant component of the day. On average, commuters in many parts of the world travel for about 20–30 min each way (irrespective of the travel mode used), but commuting times can be much greater than this (an hour or more) in large metropolitan areas. Perhaps surprisingly, the time spent traveling to and from work has changed relatively little over time, but the distance traveled has increased substantially as commuters have gained access to faster forms of transport. For instance, it has been estimated that in Britain in the period 1920–9 the average commuting distance was 6.8 km with a travel time of 30.3 min (Pooley and Turnbull, 1999), whereas in England in 2017 commuters still traveled on average for 31 min but covered a distance of 14.6 km (DfT, 2018). This article examines the ways in which the journey to work has changed over time, the ways in which it varies in relation to factors such as locality, gender, age, and occupation, and its interaction with deeper structures of cultural, social, economic, technological, and environmental change within societies. First, however, it is necessary to define exactly what is meant by both transport and commuting.

What is Commuting?

The term commuter was first used in the United States in the mid-19th century to define someone who traveled from the expanding suburbs of American cities to work in the city center, but its origins as a word that denotes the exchange of one thing for another can be traced to at least the 17th century. In its most commonly used modern form it simply means exchanging one location for another on a regular basis. However, on closer examination the concept of travel to and from work is rather more complex than this definition suggests. While the term commuter is most commonly associated with travel for paid employment, many people will travel for unpaid work of many kinds. This encompasses much activity that has traditionally been viewed as female “work” such as escorting children or essential travel related to household duties, and it may also include travel for study at school or college. In many parts of the world much labor is undertaken in fields close to the home producing food both for consumption and sale, with men and women traveling daily to tend crops, while others travel for their work or work while traveling. The rhythm of commuting can also be highly varied. Although most people travel daily, others may have a weekly commute between home and workplace while some may travel on a regular basis every month or less often. In some employment such patterns are far from regular and vary according to the availability and location of work. Finally, some work at home most or all of the time and their commute may be from one room to another undertaking both paid and unpaid activities. While the most commonly understood meaning of commuting as regular travel to and from paid employment dominates the literature, it is important to remember the multiplicity of experiences and activities that constitute travel for work in all its possible forms.

What is Transport?

To transport something simply means to move it from one place to another by any means, but in the context of commuting transport is usually viewed as the machine (most commonly a train, bus, car, or bicycle) by which people travel from their home to their

workplace. Thus, the literature is dominated by research on changing transport technologies and their impacts upon individuals and societies. However, both in the past and the present many people travel to and from their places of employment on foot, but walking is rarely viewed as a form of transport and is thus neglected in much transport planning. In some parts of the world walking is the dominant mode of transport for daily activities, and this is especially the case for women and children (Porter, 2002). I argue that walking should be given at least equal status with other forms of transport in studies of commuting and in planning transport networks. The forms of transport used for travel to work have not only varied globally over time and between countries, but also within countries by scale and density. For instance, in large rich countries such as the United States some people may commute long distances by plane on a regular basis, but this is much less common in small or poorer nations. There are also significant differences between urban and rural areas. In high-density urban environments commuting distances for some may be quite short, and are more likely to be by public transport, by bike, or on foot, whereas in rural areas and the low-density suburbs of cities commuting is most often over a longer distance and is mainly undertaken by car or public transport. Finally, with the development of new communications technologies, it is important to consider the role of virtual communications in affecting everyday travel. Many office workers are increasingly able to exchange a daily commute for work at home on some days of the week, with internet-based communication replacing daily travel. As such, new communication technologies must be viewed as another form of transport related to commuting.

Unraveling Complexity in Commuting and Transport

The analysis of transport modes and commuting is intertwined with many other themes, and is embedded within a wide array of societal structures, forming part of a complex system of networks and flows that create distinctive opportunities and resistances. In this section, I outline some of the main factors that influence the transport modes used by commuters and the fields of study relevant to their analysis. Most obviously, the transport modes used by commuters have been structured by the history of transport and communications technologies and their impacts in different places and on different segments of society. There is a tendency to assume that as new technological innovations developed they replaced the old forms of transport, but in many places and especially for more marginalized sections of society, older and traditional transport modes continued and flourished alongside the new. There is also need to consider the evolution of work practices and the ways in which transitions from, for instance, family and home-based work to factory or office-based work totally changed the structure of people's lives and travel behaviors. Working practices, the composition of the work force, and the nature of work itself all impact upon travel modes and commuting practices. Changes in urban structure and the location of both homes and workplaces have also had a major impact on commuting flows and modal choices. For instance, when most daily movement was from suburb to city center the use of radial networks of public transport was easy and normal. This was the case in US cities in the late-19th century when the term commuter was first used in its modern sense. However, as urban structures became more complex and work locations dispersed, more people were faced with complex cross-city journeys that were hard to accomplish by public transport but much easier by car. Where they could, commuters changed their modal choice. An important, but sometimes neglected, factor in analyses of transport modes and commuting is the structure of gender roles within society. In the past many societies (though not all) were strongly male dominated with commuting for work undertaken mainly by males. Women's unpaid work in childcare and house-care was not considered productive and their travel in association with these activities rarely explicitly considered. Increasingly, in at least some societies, women have entered the workforce, but it remains the case that many women continue to carry the main responsibility for family and household duties. They are thus more likely to work part time or flexibly, and to work closer to home so that their complex mix of responsibilities can be managed. Thus, the decisions that women are required to make by the societal and familial structures that exist in many societies strongly influence their commuting patterns and travel modes. Finally, none of these factors can be considered without taking into account global histories of economic development. Persistent inequalities in wealth and associated power within the global economic and political system have meant that the opportunities to adopt the most modern and efficient working practices and transport technologies have been limited. Historical and persisting global inequalities both structure and are reflected in present-day transport and commuting patterns and experiences around the globe.

Ways of Working and Commuting

There are many ways in which the topic of transport and commuting could be tackled, with probably the most conventional being to focus on each of the main transport modes. However, rather than doing this explicitly, I identify distinctly different ways of working with their associated patterns of commuting and transport modes, and consider the individual and societal impacts of each. Although the scenarios I present can be viewed as representing the stages through which many societies have changed, they are explicitly not presented as models of "modernization" or "development." Rather, it is argued that it is possible for different ways of working and traveling to sit perfectly comfortably alongside each other, and with the potential for each to wax or wane over time in a cyclical structure. Each scenario is explained through reference to examples drawn from different parts of the world at various time periods, but these are by no means the only locations or times to which they could apply.

Home, Field, Farm, and Workshop

For much of history, and in many places today, people work and live in very close proximity. For some this is a choice but for others a necessity. Women and men who farm almost anywhere in the world and at any time in the past or present live with their work. For instance on a dairy farm in northwest England accounts and other paper work are typically done in the home, the milking parlor is in the yard together, possibly, with pens for hens or geese, and travel to and from the fields is undertaken mainly on a quad bike or tractor. In poorer countries of the world much of the same pattern occurs, varying only with the agricultural economy and transport available. Much travel to tend field crops is likely to be on foot, as it would have been in the past in most locations. Small-scale industrial activity can also be carried out close to the home. The development of locally based cooperatives both in agriculture and craft industry has enhanced the financial independence of many women in, for instance, sub-Saharan Africa, with productive activities carried out in homes or nearby workshops. This is not dissimilar to the situation in much of preindustrial Europe where work on the land might be combined with small-scale manufacturing in a nearby workshop, possibly as part of a family-based dual economy where all family members contributed to the household income. In all these cases commuting is over very short distances and mostly on foot. The development of new communications technologies in the 21st century have enabled some to exchange a long commute to an office for work at home for at least part of the week, thus in some ways returning to a preindustrial system of employment and commuting. Furthermore, for women or men engaged mainly in domestic duties, whether paid as a housekeeper or *au pair* or unpaid as a housewife/husband, travel to and from work is within the home or immediate locality while carrying out everyday domestic tasks. Both in the past and the present it is important to remember that not all work requires long commutes or complex transport systems, but that much productive activity can be accomplished in and close to the home with most travel on foot. Arguably, if we wish to move toward more sustainable and energy-efficient lifestyles then the growth of employment and commuting practices that minimize transport needs is one possible solution (Banister, 2008).

The Concentration of Employment in Factories and Offices

In 19th-century Europe industrial change led to the rapid growth of larger units of production and associated commercial and office activities. This occurred first in Britain but rapidly spread through most of the richer nations of the world. The development of large-scale factory employment reconstructed the time-space prism through which many workers viewed the world. Rather than working in or close to home, at a pace and time that suited the family, factory or office employment required the presence in a specific place at particular times, with harsh penalties for not conforming to the established work routine. Working hours were usually long and it was thus essential that workers could travel easily and quickly from home to workplace. In an age before mass public transit such as in 19th-century Europe, or in poorer nations today where most cannot afford transport fares, it was and still is essential to live as close as possible to a workplace. A short journey to work is especially important when employment is casual and/or uncertain: failure to be at a workplace on time could lead to a day without income. Thus, in Victorian Britain many families continued to live in poor quality inner-city housing close to new factory employment because of the need to be able to travel easily on foot, even though when in work they may have been able to afford better housing elsewhere in a city. For much of the 19th century only those with higher incomes and more secure employment could countenance a longer commute either on foot or by horse-drawn omnibus (Dennis, 1986). In the past and the present when incomes are limited and working hours are long there is a premium on a short journey to work by the cheapest means possible.

One other consequence of the concentration of employment in larger units is increased differentiation of employment and commuting by gender, age, and skill. In the 19th century office employment was almost entirely male and most factories were dominated by a male workforce, the main exception being in textile districts where female factory labor was important. Thus, while men commuted, albeit a short distance, to work regular hours in a central location most women remained much closer to the home often engaged in work such as sewing or laundry that could be done in the home and combined with childcare and other household tasks. Factories and offices also became more hierarchical, with differentiation of skills and associated income. In general, clerks and other office workers had more regular employment than most factory workers and could thus commit a larger portion of their income to rent, allowing a longer commute to work. However, within the office, status and reward were also increasingly differentiated by age and experience as part of the gradual “professionalization” of employment. Within factories too there was differentiation between those with skills who had served a lengthy apprenticeship and those who relied on manual labor: while the former could afford to travel from the inner suburbs, the latter often were forced to live very close to their workplace. However, only the very rich could afford to live more than a 30-min walk or short bus ride from their workplace. For those on low incomes and with many competing calls on their time a short commute by whatever means is available and can be afforded remains important for many workers, especially women who may work part time and combine paid employment with childcare and household responsibilities.

The Role of Mass Transit

In the 21st century, the large-scale movement of daily commuters into major urban areas from outer suburbs and surrounding communities is a normal phenomenon. For instance, in Europe cities such as Paris, Milan, and London have daily inflows of more than one million people, with megacities such as Beijing and Shanghai in China experiencing much larger inflows. This can lead to very long daily commuting trips: commuters to Beijing and Shanghai have some of the longest commutes with an average one-way journey time of over 50 min, longer than in either New York or London. While city size and high city-center property prices are the

main determinants of long-distance commuting today, this was made possible in the 19th century by technological change. The development of mass transit systems in US cities such as Boston from the 1860s led to the growth of the so-called “street car suburbs,” from which much of the male population commuted to work in the city center on the newly developed network of trams and trolley buses. For the first time commuting by public transit became the norm for a majority of the male population of working age (Warner, 1978). Similar technologies spread rapidly to cities in Europe and elsewhere. For instance in Amsterdam a network of horse-drawn trams developed from the mid-1870s, and after 1900 when the municipality took over operation of the tram network the lines were gradually electrified and extended into growing suburbs. Upgrading of old routes and the development of new lines has continued so that trams continue to be a key element of Amsterdam’s public transit infrastructure. Not all cities that gained a tram network in the 1870s managed to retain it during the 20th century. In Manchester (United Kingdom) horse-drawn trams developed from 1877 with the first electric tram in 1901. However, by 1928 the tram network had reached its peak and the network was gradually replaced by motor buses that were seen to offer a more flexible and modern form of public transport. In 1949 all Manchester trams ceased running and it was to be 43 years before trams reappeared with the opening in 1992 of the first Manchester Metrolink line, a combination of light rail and street tram, partially utilizing existing rail tracks (Pooley and Turnbull, 2000). Today, Manchester has a reasonably dense network of trams that are seen as a sustainable and efficient way of moving large numbers of commuters around the city. A similar history has been repeated in many British cities. Urban metro lines and commuter rail networks also developed at the same time as urban bus and trams routes with most major cities gaining a dense network during the 20th century. Shanghai, Beijing, Guangzhou (all in China), and London all have metro networks of over 400 km in length, with cities such as Moscow, New York, Delhi, and Tokyo not far behind. The mass transit systems that started in the 1860s, and have evolved and become more technologically sophisticated over time, continue to carry the majority of commuters in larger towns and cities. For instance in 2011 some 69.4% of commuters in Paris traveled by public transport compared to a French national average of just 17.8% of commuter trips undertaken on public transit systems.

The Desire for Independence and Flexibility

While mass transit systems can convey large numbers of commuters quickly and conveniently from suburb to city center, they also have a number of disadvantages from the perspective of many individual travelers. They run on fixed routes and at predetermined times that may be inconvenient if they do not coincide with individual time–space schedules. They also require commuters to share space with other travelers, often in crowded compartments that lack privacy and comfort. For many commuters daily travel to work on public transit systems can also be prohibitively expensive. Travel on foot is undoubtedly the cheapest, most flexible, and independent form of transport. You can travel anywhere, at any time for almost no cost and with whoever you choose as a companion. However, expanding residential suburbs and changes in city structure meant that walking became impractical for many commuting journeys. The bicycle offers one alternative that enables the traveler to cover greater distances while retaining independence, flexibility, and relatively low cost. In Europe from the 1920s cycling was increasingly adopted as the commuting mode of choice by many men (Horton et al., 2007). This enabled commuters to travel where and when they wished, especially important for those who worked at times or in locations not well served by public transport, and cycling avoided the need to mix with other travelers. At its peak in the 1930s some 60% of all trips in the city of Berlin were by bike. However, many of the advantages that commuters sought from the bicycle could be fulfilled more easily and comfortably by the use of private motor vehicles, and as cars became more affordable bicycle use in European cities declined to be replaced by driving to and from work. Cars allowed longer journeys to be completed, enabled the easy carrying of passengers and luggage, and protected users from the elements. Their advantages were seductive as most rich countries entered the age of automobility. In the early years of motoring cars were used mainly for leisure and pleasure and not for commuting, but changes in urban structure hastened the rise of the motor car and the relative demise of the bicycle and public transit (Mom, 2014). When workplaces were mostly in the center of cities trams and buses worked well, but as employment nodes became distributed around the urban periphery workers had to make complex cross-town journeys that were much more easily accomplished by car. The dominance of motor travel occurred first in the United States but spread rapidly to Europe and elsewhere by mid-century. This trend has been seriously challenged in only a few cities such as Copenhagen and Amsterdam where today cycling forms a large component of daily commuting.

In poorer counties of the world the timing of change has differed but the trends have been much the same. For instance in much of Africa and Asia, while many continue to walk or cycle to work, or use public transport systems, motor transport has become increasingly important creating high levels of congestion and pollution. For instance, cycling accounted for around 40% of all trips in many Chinese and Indian cities toward the end of the 20th century, but rates were highest in medium-sized towns and cycling has declined markedly in the 21st century with a consequent increase in the use of motor vehicles in all locations, though the use of e-bikes has partially limited the decline in cycling. As in the past, commuting continues to be structured by gender and income. Women continue to be more likely to work closer to home and to travel on foot or by public transport, while those on low incomes seek to minimize travel costs and are often forced to endure long and uncomfortable commuting journeys at unsocial hours. In many cities the characteristics of those who walk, cycle, use public transit, or travel by car are very different. The desire for flexibility and more personalized transport can also be partially met by a variety of *para*-transit systems that exist in various guises in most urban areas. Almost all cities have taxis and the development of digital technologies has revolutionized their use in many large urban areas, but older technologies also persist with, for instance, the cycle rickshaw continuing to provide personalized transport in many Indian cities. Other semiflexible systems include dial-a-bus schemes that can be more convenient for older and less mobile travelers in rural areas and community-based car-sharing clubs. In most cities in many parts of the world there now exist a multitude of travel

options for the commuter, but in rural areas commuting choices are more limited. Most small settlements have poor or nonexistent public transport systems and thus commuters are forced to travel by car if they need to cover a significant distance.

Conclusions: The Future of Transport and Commuting

It has been demonstrated already that older technologies and transport modes can coexist alongside new technologies, but 21st-century awareness of and concern about global climate change and the quality of the urban environment may lead to the further revival of some older forms of transport and commuting behaviors. It is undeniable that the petroleum-powered automobile is a major source of carbon and produces tailpipe emissions harmful to human health. Many countries are now seeking ways to reduce these impacts, especially in urban areas. Travel by air or high-speed train also harms the environment, and although these modes are rarely used for a daily commute some people who travel weekly or monthly to work between one location and another may fly or travel by high-speed train. Commuting, often over increasing distances and by more polluting modes, has become firmly embedded in most societies and will be hard to shift, but changing societal attitudes toward the environment, especially from the younger generations, may mean that change is possible. New automobile technologies such as the use of electric vehicles and autonomous transport systems may reduce some aspects of urban pollution and carbon release, and China has been at the forefront of investment in electric vehicle technology. But these changes also bring other risks. First, they are still cars that can produce associated congestion and risks to pedestrians and cyclists. Second, unless there is a global shift to renewable electricity production the impact on carbon reduction will be limited. Third, the components of batteries, most notably lithium, cobalt, and nickel, have significant environmental costs in terms of their extraction, and disposal. There is a risk that in solving one problem we create another. One solution is simply to travel less: to restructure cities and working practices so that most people can work from home or close to home using new digital technologies, with most travel on foot or by bicycle and with longer trips by energy-efficient and carbon-neutral public transport. In effect, this would be a return to commuting patterns of two centuries ago. Some people do travel in these ways, either by design or necessity, and just as urban structures and working practices have been changed in the past so too there is no reason why creative use of new transport technologies should not enable this to occur again.

Biography

Colin Pooley is emeritus professor of Social and Historical Geography in the Lancaster Environment Centre, Lancaster University, United Kingdom. His research focuses on the social geography of Britain and continental Europe since c. 1800, with recent projects focused on residential migration, travel to work, and other aspects of everyday mobility.

Introduction

In 2019, 55% of the world's population lived in urban areas, increasing from 25% in 1950. It is estimated that by the year 2050, 68% of the world's population will be living in towns and cities (UN, 2020). If we consider absolute values (rather than just percentages) and the growth rate of the world's population from 1950 to 2050, the figure becomes even more significant.

Urban population growth and transformation of cities into megalopolises pose formidable problems in all countries. Urban conglomerations are becoming ever more common on a global basis, and there has been a sizeable increase in the number of cities, both those above one million inhabitants and those between 500,000 and 1,000,000. By 2030, the world is projected to have 43 megacities with more than 10 million inhabitants, most of them in developing regions (UN, 2020).

As the world continues to urbanize, sustainable development depends increasingly on the successful management of urban growth. Many countries will face challenges in meeting the needs of their growing urban populations as regards housing, transportation, energy systems and other infrastructure, as well as employment and basic services such as education and health care. Integrated policies are needed to improve the lives of both urban and rural dwellers, while strengthening the linkages between urban and rural areas, and building on their existing economic, social and environmental ties.

To ensure that the benefits of urbanization are fully shared and inclusive, policies to manage urban growth need to ensure access to infrastructures and social services for all, focusing on the needs of urban people for housing, education, health care, and working and living in a sustainable environment.

Therefore, the processes of urban reorganization have often entailed a division of functions, with the separation of residential from commercial/shopping areas. The emergence of out-of-town shopping malls has emphasized this separation. Subsequently, understanding the key trends in urbanization likely to unfold over the coming years is crucial to the implementation of the 2030 Agenda for Sustainable Development, including efforts to forge a new framework of urban development.

Such population concentrations and changes in the social structure, combined with the need for sustainable mobility, heighten problems connected to the purchasing of goods by end users (shoppers) and the restocking of retail outlets. Indeed, this segment of mobility significantly contributes to unsustainability as shown by the extensive literature (e.g., Russo and Comi, 2016; Iwan et al., 2018). Trips for purchases are, in percentage terms, ever closer to those of home-work, exceeding in urban areas systematic home-work trips. In the US in 1983 annual trips per household averaged 537 to/from work and 474 for shopping. By 2009 this had changed to 541 to/from work and 725 for shopping (NHTS, 2009). According to Santos et al. (2011), about 20% of all household travel and 15% of vehicle miles traveled in the US are associated with shopping. In 2014, for instance, shopping was the most common trip purpose accounting for 19% of all trips in England (DfT, 2015). Shopping travel is driven by the dynamics of the retail sector and hence highly influenced by its transformation. For example, average distances traveled for shopping trips have increased significantly in the UK over the past 20 years with the advent of out-of-town retail developments (DfT, 2015; Suel and Polak, 2017).

Besides, given that, as detailed in the sections below, this share of mobility is almost always performed by car, traffic impacts upon cities become significant. As revealed by surveys carried out in the larger European cities (Gonzalez-Feliu et al., 2012; Schoemaker et al., 2006), 69% of urban distances (veh * km) covered each day by motorized vehicles for freight transport consist of shopping trips, 24% of restocking trips (e.g., deliveries to shops, hotels, restaurants or catering activities) and the remaining 7% result from urban management (e.g., building sites, waste collection, network maintenance).

The traditional structure of restocking of neighborhood shops, and hence of buying goods in such shops, is being increasingly modified by new forms of purchase and distribution, resulting from the Internet. In the US, e-commerce sales in the third quarter of 2019 accounted for 11.2% of total sales. In the first quarter of 2010, it was 4.2% (Census, 2020). End users have modified their behavior and purchasing decisions over time, gradually switching from traditional distribution channels. Indeed, innovation in retailing and growth in online shopping infrastructure have changed the nature of shopping in response. Lee et al. (2017) have also

shown that although online shopping has grown significantly over the past few years, traditional stores still dominated the retail market share in the US in 2014.

Given the ever-increasing importance of focusing on behavioral aspects of shopping mobility and the chance to model them, the general objective of this chapter is to point out the behavioral aspects of urban shopping, mapping travel behavior of the end consumer, especially as regards mode choice.

Starting from an analysis of existing studies on shopping processes, the chapter aims:

- to provide an overview of shopping travel patterns, highlighting the shopping choices made by end consumers to purchase in store and on line (Section “Shopping Travel Patterns”);
- to analyze the shopping travel behavioral process, using a modeling framework that allows a linkage between end-consumer choices and restocking choices made by retailers, useful for further urban freight transport analysis (Section “Shopping Travel Patterns”);
- to outline mode choice for shopping and point out the factors that affect it (Section “Factors Affecting Shopping Mode Choice”).

Finally, conclusions and the road ahead are drawn in Section “Conclusions”.

Shopping Travel Patterns

Below, we focus on freight trips due to consumer behavior and not on the overall behavior of consumers as regards shopping (for purchases). This initial restriction is required in order to differentiate the contents of this contribution from studies concerning purchasing decisions which constitute a broad field of research for all those dealing with marketing and related sciences.

First let us recall the main aspects of the structure of the shopping process in order to highlight the phases that entail movements of goods and users. Below we only deal with phases that are directly correlated with goods movements. The decisional sequences in the shopping process have been investigated elsewhere. Here, we refer to the literature revisited by [Mokhtarian \(2004\)](#) and [Russo \(2013\)](#), since its breakdown allows the phases connected with goods movements to be identified. The overall phases are: desire; information gathering and receiving; trial/experience; evaluation; selection; transaction; delivery/possession; display/use; return.

[Mokhtarian \(2004\)](#), moving on from [Couclelis \(2001\)](#), identified three main shopping phases: before, purchase, and after, each of which must be carried out in-store or by e-commerce, obtaining $2^3 = 8$ possible patterns. The eight combinations obtained define as many types of users:

- the traditional shopper who performs the three phases inside the shop (store/store/store),
- the innovative consumer or cybernaut who conducts all the phases by internet (e-commerce/e-commerce/e-commerce),
- the new types like the careful, well-informed user (e-commerce/store/e-commerce),
- the bargain hunter or free rider (store/e-commerce/store).

An even more complex segmentation is proposed by [Cao \(2012\)](#) who considers 16 alternatives to compare e-shopping and store shopping, starting from the basic four indicated by Mokhtarian (2004): Information, Trial, Transaction, and Delivery.

These segmentations are particularly important because they allow consumer behavior to be first fragmented and then reconstructed in respect of the increasingly imposing use of purchase channels connected with the Internet. They also highlight the current and potential impact of the Internet upon all the phases of the shopping process. The above segmentations, and the others found in the literature, do not allow direct specification of trips that occur in relation to the consumption of goods. Although they may be used as a starting point, further initial definitions should be set and specific hypotheses introduced on the patterns of movements and the behavior which generates them. This task lies beyond the scope of this chapter; for more details refer to [Russo \(2013\)](#) and references quoted therein.

In-Store Versus On-Line Shopping

Shopping consists of a heterogeneous set of activities and involves many different behavioral mechanisms with several implications on mobility ([Girard et al., 2003](#); [Mokhtarian, 2004](#); [Visser and Lanzendorf, 2004](#); [Rotem-Mindali and Salomon, 2007](#); [Russo, 2013](#); [Suel and Polak, 2017](#)). In-store shopping as part of daily life enables individuals both to acquire certain items and to fulfill needs for social interaction and entertainment. Individuals also maximize their daily trip chain by including shopping activities in their trips ([Mokhtarian, 2004](#)). Such personal and social needs consist of aspects such as fulfillment of social interaction, or social experiences outside home, communication, attaining status, and getting pleasure from bargaining ([Joewono et al., 2019](#)).

The changes to daily life in the digital era because of the development of ICT have altered the ways in which people carry out activities, including shopping. [Mokhtarian and Salomon \(2001\)](#), [Mokhtarian \(2004\)](#), [Hsiao \(2009\)](#), [Nuzzolo and Comi \(2014a\)](#), and [Schmid and Axhausen \(2017\)](#) have reported the effects of ICT on shopping and travel behavior. E-commerce not only has implications on individual mobility, but also on the complementary side, namely freight restocking ([Russo, 2013](#)). The above studies showed that ICT does not necessarily replace all in-store shopping or other trips, and concluded that: (1) only certain factors related to social and personal motivation can be replaced by ICT services (e.g., the latest trends, fashions, and innovations) while

others cannot (e.g., social interactions); and (2) rates of in-store shopping remain solid, attracting individuals in certain goods sectors, such as groceries (Farag, 2006; Farag et al., 2007; Comi and Nuzzolo, 2016).

As stated above, several authors over the years have explained the attractions of in-store shopping travel and shopping activities. They showed that in-store shopping allows sensory information to be obtained by seeing, trying, feeling, smelling, tasting or manipulating the desired items, providing individuals with full information about and confidence in the product. Besides, it has been found that a lack of trust is a barrier to online shopping. For instance, individuals (end consumers) tend to choose established stores with many years of trading in their town rather than e-shopping retailers, who are unknown and may go out of business without warning. Lastly, the instant possession of items is important; individuals can immediately own the purchased items, rather than waiting for the items to be delivered after e-shopping (Joewono et al., 2019). For the above reasons, some freight types, such as electronic items, attract more e-purchasing than others (Comi, 2020).

In addition to the dimension of competitiveness of in-store shopping as opposed to e-shopping, external components of the in-store shopping process also have substantial influence. Shopping as a physical activity provides opportunities to meet needs for social engagement, since going shopping offers time to enjoy oneself, either alone or with friends and family. In-store shopping can also be a source of entertainment, rather than solely a maintenance activity. The function and facilities provided by modern stores (e.g., restaurants, theatres, cafés, etc.) present positive opportunities for enjoying in-store shopping. Furthermore, some shopping trips form part of trip chains for other purposes (Mokhtarian, 2004; Comi, 2020).

Travel Pattern

Individual behavior aiming to fulfill needs and desires is manifested in certain activity and travel patterns within the constraints of time and space. Daily activities (mandatory or discretionary) require individuals to make decisions about the location, participation, timing, and duration of such activities (Susilo, 2005). Various needs and desires among individuals result in diverse activity arrangements and travel patterns, and this is a topic of interest even if the literature in question is far from extensive (Axhausen et al., 2002). Moreover, the pattern of travel to support shopping activities is subject to considerable variability. Differences across individuals in the variations of their shopping travel patterns across days (e.g. day-of-the-week evolution) as well as the heterogeneity of individual characteristics have also been pointed out (Sun et al., 2017). For example, Kim and Park (1997) found that routine shoppers are identified as having high opportunity and search costs, which are represented by four demographic variables (i.e. gender, employment status, level of education and whether household has children below 6 years of age).

Moreover, land use plays an important role in spatio-temporal constraints on individuals. The structure and characteristics of the built environment can influence the way in which individuals participate in activities, due to their effect on the location of such activities. The link between the built environment and travel behavior has been widely investigated, amongst others by Ewing and Cervero (2001), Reilly and Landis (2003), Schwanen and Mokhtarian (2005), Handy et al. (2005), and Cao et al. (2006).

Based on the above statements and following Comi et al. (2014), and the fact that about 70% of daily shopping trips are home-based (i.e., ring trips) and few are part of trip chains (combining trips undertaken for different purposes), the global demand function for simulating travel for shopping can be decomposed into sub-models, each related to one or more choice dimensions: trip production, shop type and location, mode and path choice. Of course, such a general framework can receive input from upstream modeling frameworks which identify the needs to buy (purchase modeling; Comi, 2020) (Fig. 1).

Trip production or trip frequency estimates the mean number of “relevant” trips undertaken for shopping by a given category of end consumers (e.g., students, employees). Trip generation is mainly affected by socio-economic characteristics and land-use patterns (or the physical characteristics of the area; Cubukcu, 2001; Yao et al., 2008; Nuzzolo et al., 2014), as well as by freight type (e.g., foodstuffs, clothing).

The *shop type and location stage* simulate the choice of a “shop” type (e.g., nearby/small shop, local market, hypermarket) and a destination among possible alternatives where purchasing can be carried out (e.g., shopping areas/zones; Gonzalez-Benito, 2004;

Figure 1 Shopping travel: modeling structure (based on Comi et al., 2014).

Nuzzolo and Comi, 2014a). Such a decision can be influenced both by the built environment and by socio-economic attributes. For example, younger consumers prefer large retail outlets (even if far away) as they may be driven to search for special prices, while the elderly are more devoted to small retail outlets located nearby (Nuzzolo and Comi, 2014a and b).

The *mode choice stage* simulates the fraction (probability) of trips made by end consumers using a given transportation mode. Mode choice is a typical example of a travel choice that can be modified for different trips in which performance or level-of-service attributes have considerable influence as well as shoppers' attitudes, departure time and attractivity of destination (Vrtic et al., 2007; Suel and Polak, 2017; Ramezani et al., 2019; Comi, 2020).

The *path used* should also be investigated. Path choice behavior and the model representing it depend on the type of service offered by the different transport modes. Several models have been proposed both for private or public transport. For an overview we refer to Cascetta (2009) and Nuzzolo and Comi (2018).

Given that shopping trips are mainly performed by car and one of the main policies of urban/regional planners is to push users towards more environment-friendly modes (SUMP 2019), the factors that affect mode choice are pointed out below.

Factors Affecting Shopping Mode Choice

As said, mode choice is a typical example of a travel choice that can be modified for different trips in which performance or level-of-service attributes have considerable influence. Below, the empirical evidence from different urban contexts worldwide is recalled; a behavioral choice model for shopping is then presented.

Empirical Evidence

Some examples of the investigation of shoppers' attitudes to the various transport modes for shopping purposes may be found in Vrtic et al. (2007), Bilková et al. (2016), and Joewono et al. (2019), who analyzed modes for shopping by applying discriminant analysis to explore the profiles of end consumers/shoppers. The study showed that the *private car* is the most typical mode used by shoppers to reach the most frequently visited grocery store. This confirms the attitudes revealed in the past: one of the first studies on shopping mode choice was performed by Marjanen (1995) who pointed out the influence of *socio-economic characteristics* of shoppers. Marjanen (1995) analyzed the shopping behavior of consumers in Turku, Finland, finding that the use of cars for shopping trips increased with income and family size. Marital status was also found to have a significant effect: those who were married or living together used cars more often than those who were single. However, *gender* was not found to be a significant factor. *Education* was also found to be a significantly influencing factor as the better educated were found more likely to use a private vehicle. Handy (2000) also compared mode choice behavior based on socio-demographics and *household* characteristics. Comi and Nuzzolo (2014), through some data collected in Rome (Italy), found that younger users (i.e., between 15 and 29 years old) present the highest share among those using transit (Table 1). The average travel time by transit was about 35 min, while by car it was about 24 min and on foot about 14 min.

In addition, Meena et al. (2019), focusing on shopping activities in Mumbai, revealed that the percentage of car usage increased with the higher *age* group. The age cohort of 18–30 years are physiologically more active; hence the highest percentage of public transport and two wheeler (referring to motorcycles only) usage were reported for this age group as compared to the other age groups.

Income was also shown as one of the main factors influencing the choice of private cars for shopping. Although, in some developed countries the trend is to limit car ownership and financial status cannot be derived from this variable, generally the choice of car use directly indicates the affluence and financial status of users in terms of car ownership.

El-Bany et al. (2014) investigated the effect of bus rapid transit (BRT) as a hypothetical mode with respect to existing modes (car and taxi) by using a stated preference (SP) technique to analyze the effect of socio-demographic characteristics on the mode choice behavior of shopping trips. The results from the study concluded that income is the most dominant variable affecting mode choice behavior in Port-Said city.

Joewono et al. (2019) pointed out the relationships between shopping *expenditure* and mode in developing countries. Shoppers who spend little money are more likely to walk or cycle (i.e., to shops close by) to reach their shopping location than to use a private car. In contrast, shoppers who spend more tend to travel by car. This supports previous findings on the strong relationships between income and car availability (Marjanen, 1995; Meena et al., 2019).

Table 1 Distribution of weekly shopping trips by age and transport mode (Comi and Nuzzolo, 2014)

	<i>Under 29 years</i>	<i>30–64 years</i>	<i>Over 64 years</i>	<i>Average</i>
Private vehicle (e.g., car)	67%	78%	71%	74%
Transit	14%	4%	2%	7%
On foot	19%	18%	27%	19%
Total	100%	100%	100%	100%

Table 2 Mode shares for weekly purchase trips (Nuzzolo and Comi, 2014a)

	<i>Travel distance</i>		
	<i>Less than 1 km</i>	<i>Between 1 and 2 km</i>	<i>More than 2 km</i>
<i>Small retail outlet</i>			
<i>On foot</i>	37.7%	7.1%	6.6%
<i>Private vehicle (e.g. car)</i>	59.6%	79.6%	62.3%
<i>Transit</i>	2.7%	13.3%	31.1%
Total	100.0%	100.0%	100.0%
<i>Medium-size retail outlet</i>			
<i>On foot</i>	32.5%	12.1%	12.5%
<i>Private vehicle (e.g. car)</i>	66.5%	72.7%	68.8%
<i>Transit</i>	1.0%	12.1%	18.8%
Total	100.0%	100.0%	100.0%

<i>Private vehicle (e.g. car)</i>	87.3%	92.4%	92.9%
<i>Transit</i>	3.9%	5.1%	7.1%
Total	100.0%	100.0%	100.0%

Jiao (2016) showed that end consumers' attitudes toward travel mode, and the network distance between homes and retail outlets exerted the strongest influence on travel frequency while urban form variables only had a modest influence. The study showed that frequent shoppers were more likely to use alternative transportation modes and shopped closer to their homes, and infrequent shoppers tended to drive longer distances to stores and spent more time and money per visit.

According to data collected in Rome (Comi, 2020), the shares among the three main city modes (i.e., on foot, car, and transit) show that, as expected, the main transport mode used is car: its share increases when shop size and trip length rise (Table 2). Younger users account for the highest share of those using transit. The average time spent traveling by car was about 24 min, by transit about 35 min and on foot about 14 min. Besides, it emerged that 74% of users use private vehicles and only 7% use transit (e.g., bus, metro; Tables 3 and 4).

Fun and Enid (2006) analyzed shoppers' perceptions of various public transport modes in Hong Kong, namely bus, west-rail, mini-bus, taxi, and mass-transit railway (MTR and KCRC). The study concluded that shop characteristics and shopping purpose of the trip maker affect respondent's mode choice. Similar results were obtained by Newmark et al. (2004) who analyzed the change in shopping travel behavior before and after the construction of four new shopping malls in the city of Prague, and by Ding et al. (2014) who analyzed the joint choice behavior of shopping destination and travel-to-shop mode for the study area of the

Table 3 Distribution of weekly shopping trips by type of retail outlet and transport mode (Comi and Nuzzolo, 2014)

	<i>Private vehicle (e.g. car)</i>	<i>Transit</i>	<i>On foot</i>	<i>Total</i>
Small retail outlet	66%	11%	23%	100%
Medium retail outlet	68%	4%	28%	100%
Large retail outlet	91%	5%	4%	100%
Total	74%	7%	19%	100%

Table 4 Distribution of weekly shopping trips by activity at origin and transport mode

<i>Activity at origin</i>	<i>Private vehicle (e.g., car)</i>	<i>Transit</i>	<i>On foot</i>	<i>Total</i>
Home	77%	5%	18%	100%
Work/Study	73%	9%	17%	100%

Total	74%	7%	19%	100%

Maryland-Washington DC region. They found that high parking cost at the shopping centers significantly impacted the mode choice behavior of car users.

Suel and Polak (2017) indicated that attractiveness of the walking alternative declines with the number of items in the basket (i.e., walking mode becomes less attractive for large basket shopping). Public transport also proved attractive, suggesting that walking and public transport modes are preferred to driving after other effects are accounted for, which might partially be related to lower costs associated with walking and public transport use. Further, the inconvenience associated with the driving mode due to parking availability and fees might be influential. Public transport might also be attractive for certain routes, although time spent on public transport is associated with more discomfort when compared to driving or walking. For public transport mode, increasing accessibility (as measured by the interaction with the variable for the number of stores within a 45 min travel time) reduces the negative effect of choosing public transport. In-depth analyses showed that driving becomes less attractive when one has several options within easy reach of the home location.

A Probabilistic Behavioral Mode Choice Model

According to data collected in the city of Rome (Comi, 2020, to which readers can refer for obtaining survey details), a binomial logit model was estimated. The probability (or fraction) $p[m/od]$ that users select mode m to travel from zone o to zone d for shopping can be calculated as follows:

$$p[m/od] = \exp(V_{m/od}) / \sum_{m'} \exp(V_{m'/od})$$

where $V_{m/od}$ is the systemic utility associated to the alternative m given the origin-destination pair od . In particular, the systemic utilities are expressed as follows:

- car

$$V_{car/od} = -0.122 \cdot T_{car/od} - 0.252 \cdot C_{car/od} + 2.682$$

$\begin{matrix} (-3.21) & (-2.76) & (1.98) \end{matrix}$

- transit

$$V_{transit/od} = -0.032 \cdot T_{transit/od} - 0.786 \cdot C_{transit/od}$$

$\begin{matrix} (-2.45) & (-1.99) \end{matrix}$

where T is the travel time expressed in minutes by *car* or *transit*, while C is the travel cost in Euros. The value in brackets refers to t -stat value. ρ^2 is 0.44. Furthermore, it is important to note the different VOT (Value-Of-Time) values obtained for car and transit, 29€/h and 2.40€/h, respectively, which confirms the findings explained in the earlier section.

Conclusions

Understanding travel mode for shopping becomes crucial for supporting city planners in improving city sustainability and liveability, given that shopping accounts for the second most frequently undertaken trips in most cities and regions. It is widely accepted that there is heterogeneity in shopping travel mode choice due to different factors, taking the influence of telematics into consideration. The literature shows that a number of socio-demographic, psycho-social and travel factors, as well as the built environment, affect shopping trip mode choice. Therefore, there is a need to study diversification in grocery shopping location and frequency that can correctly guide consumer demand and provide some insights for policy making. For example, higher exposure to dense, mixed use and green areas increases the propensity to use more sustainable modes of transportation for shopping trips, especially among older adults.

In addition, travel time was found to have a significant effect on mode choice behavior, as expected. The number of accompanying persons greatly impacted mode choice behavior for private vehicles as well as shopping basket size. Other socio-demographic characteristics like the type of occupation of the individual, age and gender were significant for respective mode utilities.

The indications from the literature can be considered to provide a useful shopping-related sustainability overview for city authorities and experts when designing measures for shifting consumers to more sustainable transport and needing to identify the main factors impacting non-systematic travels. Such an analysis could contribute to a more effective and rational planning process, helping city planners or administrations to select environmental/green measures expected to perform best according to the city's main characteristics. Therefore, the proposed analysis may be a useful preliminary guide when there is the need to ascertain whether a successful approach in one city can be transferred to another.

Indications for further analysis may also be outlined. First, the existing literature mainly considers only grocery shopping, without covering other daily activities. Therefore, future studies should investigate in greater depth grocery shopping as part of the

user's entire daily activities. Second, research should aim to investigate the extent of grocery shopping from day to day for a whole week, distinguishing between durable and nondurable goods as well as daily/weekly consumption purchases. Such extended studies may provide knowledge allowing researchers/planners to suggest how transportation systems should be managed in the digital age with its rapidly occurring changes. Third, suitable measures of travel demand management to support shopping activities should be explored with a view to making transport in question more sustainable.

Glossary

Community severance “Transport-related community severance is the variable and cumulative negative impact of the presence of transport infrastructure or motorized traffic on the perceptions, behavior, and well-being of people who use the surrounding areas or need to make trips along or across that infrastructure or traffic.”

Gig economy A gig economy is a labor market characterized by short-term contracts and self-employed workers, rather than permanent jobs.

Good mental health “A state of well-being in which every individual realizes (their) own potential, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to (their) community.”

Intersectionality The concept that a person or group of people can be affected by a number of disadvantages and discriminations (e.g., due to their gender, race, and age)

Morbidity Having a disease or symptoms of disease (or a state outside normal health and well-being); the amount of disease in a population

Mortality Deaths or death rates

Introduction

Transport has a wide range of impacts on health, and on inequalities (Mindell et al., 2011a; Cohen et al., 2014); these vary by travel mode. This chapter is organized as follows: Transport Modes describes the key elements of different transport modes before the further sections discuss the various key health impacts related to these. Other Benefits of Active Transport outlines how travel modes impact on health inequalities and lack of social justice, before Inequalities in Transport Modes and Health concludes with a brief mention of potential health considerations of future transport options currently being encouraged.

Transport Modes

Active Travel

Active travel is defined as using human-powered modes of transport. The most common modes are walking and cycling. Other forms of active travel include skateboarding or using a non-motorized scooter. More recently, electric-assisted pedal bicycles (e-bikes) are becoming a popular form of active travel in many high-income countries.

Walking

Walking is a familiar low-cost activity that does not require specialized equipment and is a readily available mode of transport for most individuals. Walking is a feasible form of transport for short trips. For longer trips, walking can be combined with motorized forms of transport such as public transport or private car, with walking included at each end of the travel journey.

Cycling

Compared with walking, cycling is faster; covers greater distances; requires greater motor skills; and has more specific infrastructure requirements. In many high income countries, cycling for transport is less prevalent than walking. Cycling rates for transport have declined in most countries globally over the last several decades. Exceptions to those trends are countries with significant investment in extensive cycling-friendly infrastructure, flat topography, and such as Belgium, the Netherlands, and Denmark.

Electric Bikes (e-Bikes)

In recent years, electric bikes, or e-bikes, have emerged as new forms of transport in many high-income countries. Electric bikes are very similar to regular bicycles, with the addition of a battery and motor. Data on prevalence of e-bikes usage in different countries is limited at this time due to some countries, such as The Netherlands, classifying them in the same category as regular bicycles.

According to the European Cyclists' Federation, e-bikes must:

- 1 Have a maximum speed of 25 kph
- 2 Have a maximum power output of 250 watts; and
- 3 Engage the motor only when the rider is pedaling.

In countries with a strong cycling tradition, most users of e-bikes that meet this definition are older adults or patients being introduced to cycling (who lack the strength, ability or confidence to ride a standard bicycle) and commuters with a particularly long or strenuous journey. However, in other countries, e-bikes are being used predominantly by young males as a cheap form of motorized travel, with little regard for their or pedestrians' safety. In many cases, they exceed the speed limits recommended by the European Cyclists' Federation and are driven by the motor with no cycling (and are really electric motorbikes, but mostly ridden by adolescents and young adult males).

Public Transport

Public transport covers a wide range of options that enable members of the public to access assistance to travel to destinations on payment of a fare, usually on fixed routes. The most widely used public transport modes are buses; trains, light rail, and trams vary more in their availability. For longer journeys, public transport that is affordable, accessible, acceptable, and appropriate can bring the benefits of access with fewer adverse effects imposed on others.

Private Motor Vehicles

Private motor vehicles are often said to provide the most freedom to travel for their owners compared with other travel modes. Due to convenience, speed, and independence, travel by private motor vehicles dominates travel preferences of most age groups. For families, travel by private motor vehicles facilitates trip chaining. For example, parents may be choosing to travel by car to drop off and/or pick up children from school on the way to/from work. However, as motorization increases, traffic congestion can increase traveling times to longer than other travel modes. Despite the freedom and convenience that traveling by car offers, high rates of private motor vehicle travel has a number of negative consequences for health and the environment that are discussed later in this chapter.

Shared Mobility

Taxis, Minicabs, and App-Based Private Companies

Taxis (which may be pedal-powered or motorized), minicabs, and app-based private companies such as Uber and Lyft charge passengers for bespoke journeys without fixed routes. In low-income countries, motorcycles are a common form of taxi and are often referred to as public transport. Licensing regulations differ between countries and types of motorized companies, with greater passenger protection against assault for licensed versus unlicensed drivers.

The "gig economy," characterized by being self-employed or having short-term or "zero hours" contracts is also associated with adverse health effects for those workers. This is the typical labor market for these drivers.

Car-Pooling and Public Hire Bikes and E-Scooters

Unlike taxis, these transport modes do not generally provide door-to-door access as the hired vehicle needs to be accessed before it can be used and then parked afterward. Thus there is often some active travel before the main stage of the journey and may be at the end as well. Hire bikes and e-scooters not requiring a specific docking station can be left anywhere, increasing convenience for the user but potentially causing trip hazards for pedestrians and reducing the opportunities for physical activity for e-scooters.

Well-Being

What is Well-Being?

The World Health Organization (WHO) defines good mental health as "a state of well-being in which every individual realizes (their) own potential, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to (their) community." Studies of commuters have consistently found improved mental well-being among those who commute by cycle or foot, with higher ratings for health, confidence and positive mood (affect). However, cycle commuters in some studies scored higher on distress and fear and lower on security.

Public transport commuters vary in how their journey affects well-being. Traffic congestion, poor reliability, overcrowding and other adverse impacts on comfort, and stress each reduce well-being among public transport users. Generally, car commuters report the lowest well-being.

Regardless of travel mode, enhancing the experience of travel could improve well-being. In addition to health benefits, increasing rates of active travel contribute to increasing the liveability of towns and cities and addressing health inequalities.

Green and Blue Environments

“Green streets” encourage walking because they are a more pleasant environment compared with traditional traffic-dominated roads. Being in, or even seeing, green environments improves mental health and well-being and can speed recovery from illness and surgical procedures. There is increasing evidence that “blue environments” (rivers, canals, lakes, coasts) have similar effects. Although these may be considered more relevant in the context of leisure than travel, journeys made through or past green or blue environments will benefit health.

Older people encouraged to take up cycling on e-bikes improved their mental health more than those using conventional bicycles. This may be due to greater stimulation from greater exposure to the natural environment.

Physical Activity

Travel Modes and Physical Activity

Active Travel

Both walking and cycling, the two most common modes of active travel, are associated with increased physical activity. The substantial health benefits of walking and cycling for transport outweigh detrimental effects of air pollution exposure and traffic incidents (Mueller et al., 2015).

Walking for transport is associated with higher levels of physical activity in children, adolescents, and adults. Although some studies suggest that walking to school may also be associated with increased fitness in children and adolescents, the current evidence is inconclusive.

Cycling for transport is also associated with higher levels of physical activity. In addition, children who cycle for transport also have higher levels of fitness compared with their peers who walk or use motorized transport to school.

Despite electrical assistance, e-bikes that meet the European Cyclists’ Federation definition provide moderate-to-vigorous intensity of physical activity, depending on their usage. Some individuals use e-bike as a starting point, or a “gateway” to being more physically active. However, the most common reasons for purchasing and using e-bikes include increasing the cycling speed and/or range/distance; reducing the effort of cycling in general and up hills; environmental benefits (compared with other motorized travel modes); and increased opportunity to cycle for individuals with health issues.

Walking Versus Cycling

Walking and cycling are often considered together under the term “active travel.” Although most of the health benefits associated with these modes are similar with respect to increasing daily physical activity, walking and cycling are influenced by different individual, social, environment and policy factors (Mandic et al., 2017). For example, compared with walking, cycling is generally regarded as less safe. However, the actual risk of an injury or a fatal event as a result of cycling on the road is much lower than the perceived risk. In children and adolescents, rates of cycling to school and other destinations are influenced by their preferences to cycle (or not); parental confidence in their child’s cycling skills; parental and children’s concern about traffic safety; and social support for cycling from parents and peers. Therefore, interventions for promoting active travel need to consider different approaches for encouraging walking or encouraging cycling.

Public Transport

Public transport is a form of motorized transport. However, most journeys by public transport involve walking- or sometimes cycling- at one or both ends of the journey, to and/or from the bus stop or station. Thus, public transport is sometimes also included in the term “active travel.” Public transport users take 30% more steps per day compared with individuals who rely on cars for transport. Walking or cycling to/from public transit can be sufficient to meet adults’ weekly physical activity guidelines.

Private Motor Vehicles

Individuals traveling using private motor vehicles are sedentary during the journey, and often travel door-to-door, with minimal walking at either end. Cars and car-users generally impose adverse health consequences on others, exacerbating health and social inequalities. In addition, high volume of traffic and/or high traffic speed acts as a major barrier to active travel, especially among children and adolescents.

Effects of Active Travel on Mental and Physical Health

Reliance on active travel contributes to maintenance of healthy body weight and better mental and physical health outcomes. Physical activity, including from active travel, reduces risks of developing or dying from obesity, diabetes, circulatory diseases (heart disease, stroke), some cancers, osteoporosis (bone-thinning), and depression, and increases mental well-being. For example, in walkable neighborhoods, adults using active travel have lower prevalence of diabetes and obesity compared with their peers who rely on motorized transport. Adults who change transport mode from driving to active commuting lose weight; those who change from active commuting to car use increase weight; public transport users lie between these two groups (Martin et al., 2015).

Active travel contributes to creating liveable town and cities, designed for people to enjoy, and therefore contributes to increasing social capital. Active travel facilitates social interactions with peers, including casual contacts such as greeting neighbors; it connects individuals with their neighborhood environment; and can both improve neighborhood safety and contribute to better mental health.

Air Pollution

Air Pollutants

There are 4.2 million deaths each year globally due to ambient (outdoor) air pollution, although a recent European study suggests this may be a considerable underestimate. The WHO has estimated that worldwide, ambient air pollution accounts for—29% of cases of deaths from lung cancer; 43% of all deaths and disease from chronic obstructive pulmonary disease (COPD, previously known as chronic bronchitis and emphysema); 17% of deaths and disease from acute lower respiratory infection (e.g., pneumonia); 25% of deaths and disease from ischemic (or coronary) heart disease (e.g., heart attacks), and 24% of all deaths from stroke.

Both short- and long-term exposure to air pollution increases the risks of developing cardio-respiratory diseases and also causes exacerbations, increasing morbidity and mortality from these diseases. For example, air pollution exposure can increase the frequency and severity of acute asthma attacks, increasing the need for medication and the number of hospital admissions. More recently, evidence has also shown that air pollution also increases the risks of obesity, diabetes, neuro-developmental conditions in children, and neuro-degenerative conditions (such as dementia). Exposure to the major air pollutants can reduce lung function. Maternal exposure is also associated with adverse birth outcomes, particularly low-birth weight, with its attendant adverse health impacts for the child ([RCP, 2016](#)).

The pollutants with the greatest effects on the public's health include particulate matter (PM), nitrogen dioxide (NO₂), ozone (O₃), and sulfur dioxide (SO₂). Most evidence is available for PM less than 10 µm (PM₁₀) and less than 2.5 µm diameter (PM_{2.5}). The WHO estimates that 91% of the global population breathe polluted air, with 80% of urban residents being exposed to ambient air pollution that exceeds the WHO limits.

Other air pollutants include volatile organic compounds (VOCs) from fuel. One of these, benzene, is associated with increasing the incidence of leukemia. Particulates may also carry other irritants and allergens into the nose and lungs, increasing asthma and allergic rhinitis (hayfever).

PM, SO₂, and NO₂ are generated by combustion of fossil fuels. In general, concentrations of pollutants are highest inside motor vehicles, compared with the sides of the road where people walk and cycle, especially in congested traffic where a vehicle's air intake is directly behind another vehicle's exhaust (tailpipe). Buses usually have concentrations that are lower than those found within private vehicles but higher than at the side of the road. However, when breathing more deeply or faster, such as when walking or cycling briskly or uphill, pedestrians' and cyclists' dose of pollutant may be higher than in motorized travel. It is thus important to select routes for walking and cycling and for their infrastructure that are as distant as possible from motor traffic flows but without major inclines. Metro systems also have very high levels of PM that exceed WHO limits. The majority of these PM are iron, from friction between the wheels and the rails when braking. It is currently unknown whether these PM have similar or fewer health impacts than anthropogenic PM from fossil fuel combustion.

PM also arise from brakes and tires, and are thus emitted from electric vehicles as well. Electric vehicles use energy generated remotely. They are not non-polluting, unless the energy is from a renewable source, but the pollutants emitted are generally remote from major populations and thus have fewer health impacts than those generated in urban streets.

Greenhouse Gas Emissions

In many countries worldwide, motorized transport is a major or the leading source of greenhouse gas emissions, leading to climate change. In the past decade, there has already been a large increase in extreme weather events, including floods, hurricanes, and tornadoes, leading to widespread destruction of housing and other infrastructure and, in some cases, to loss of life. In general, low-carbon transport policies to mitigate global climate change would have the co-benefits of improving health ([Mindell et al., 2011b](#)).

In addition to the obvious health impacts of these extreme events, climate change has other serious health impacts. Rising temperatures bring tropical diseases to more temperate zones, due to spread of areas suitable for the insect vectors to live. Dengue fever is increasing in the countries where it is endemic. Both drought and floods can destroy or greatly reduce food crops, leading to hunger and malnutrition. [Fig. 1](#) shows some of these direct and indirect effects, and the factors that can magnify or reduce these impacts. There are likely to be global inequalities in the consequences of climate change. Greenhouse gas emissions from motor vehicles predominantly come from high-income countries, but the health consequences will afflict poorer countries more, with their generally larger populations but fewer resources. Many of the poorer countries are low-lying, so flooding will be even more devastating.

Noise

Motor vehicles are the main source of noise in urban areas in most, if not all, countries. Noise is an irritation that reduces well-being. Noise can also interfere with sleep and concentration, of particular concern, if they impact on mental health. They can also impact

Figure 1 The direct and indirect effects of climate change on health and well-being. Source: Watts et al. (2015)

educational attainment, which is one of the most important social determinants of adult health. Children in classrooms on the noisy side of schools near airports, for example, do less well in tests than their otherwise similar peers in the quieter classrooms. Equally seriously, noise exposure increases blood pressure. Persistently raised blood pressure (hypertension) increases the risks of developing circulatory diseases, particularly heart disease and stroke, and of dying from those diseases.

Noise generated by vehicles has the small health benefit of alerting individuals with adequate hearing to the presence of an approaching vehicle, reducing the likelihood of a collision. The United Kingdom is therefore introducing a requirement for electric vehicles to generate sound at low speeds where the vehicle would otherwise be almost silent. The silence of cycles, scooters and skateboards is also a cause of concern for some pedestrians.

Injury

Road travel injuries are the eighth leading cause of death globally. Worldwide, there are 1.35 million deaths on the road each year in addition to 20–50 million people injured. Many of those injured remain with long-term disabilities, particularly in low-income countries where rehabilitation services are sparse, inaccessible, and/or unaffordable. In many cases, there are no or inadequate welfare payments so if the injured person can no longer work, even subsistence is difficult for them and their dependents, further damaging their own and their family members' health.

Injury rates vary widely by mode but even more by country, gender, age, and deprivation (Feleke et al., 2018). In most low and many middle income countries, numbers (or estimates) are available for deaths and serious injuries but denominators for rates are population figures, at best. In most high-income countries, rates of road travel injuries can be calculated using travel data to provide fatality or injury rates per trip, per billion kilometers (bnkm), or per million hours traveled by a particular mode. This enables better "like-for-like" comparisons.

Country

Low- and middle-income countries have 60% of the world's vehicles but 93% of the world's road travel deaths. The death rate is highest in Africa. Death rates vary from 2.7×10^{-5} population in Norway to 35.9×10^{-5} population in Liberia.

Gender

Males consistently have higher fatality rates than females, in low- and in high-income countries and for every mode. Globally, almost three-quarters of road traffic deaths occur in males under the age of 25 years.

Age

Road travel injuries are the leading cause of death for people aged 5–29 years but older people have much higher injury and death rates than other adults. Although there are reasons for considering older people to be at greater risk of involvement in a collision (impaired hearing, vision, balance, cognition and/or slower reaction times), the main reason for this higher road travel death rate is probably poorer preexisting health. Greater frailty and more preexisting conditions reduce their physiological reserve and their capacity to recover from injury. In Great Britain, pedestrians and cyclists in their 70s and 80s had 10 times the mortality rates bnkm^{-1} than those in their 40s.

Deprivation

People who live or are traveling in more deprived areas have a greater risk of injury and death than their more affluent peers. In Great Britain, this applied to drivers and pedestrians but not to cyclists. In low-income countries, pedestrians, motorcyclists, and cyclists make up the majority of those injured or killed on the roads.

Travel Mode

More than half of the people killed worldwide in road travel collisions are pedestrians, cyclists, or motorcyclists. This is particularly the case in low- and middle-income countries with relatively few journeys made by motor vehicle. The lack of infrastructure, regulation, and enforcement exacerbates the vulnerability of people who have no option but to walk or cycle. Countries with excellent cycling infrastructure have very low-fatality rates among cyclists. Motorcyclists generally have a fatality rate an order of magnitude higher than that of other travel modes, even in high-income countries.

In high income countries, public transport is generally the safest form of transport but elsewhere, overcrowding, poor design and maintenance, and lack of regulation, and enforcement contribute to high risks of collision and of injuries. Car occupants are the main group killed in countries where private vehicles predominate, because of their sheer preponderance of numbers.

The pattern of fatality and injury rates with age is J-shaped for walking and cycling but U-shaped for car occupants. A study in Great Britain found that not only were young male adults safer when cycling than driving, so were all the other road users.

Perception

Perceptions of the risks of injury or death when cycling are greatly exaggerated. As cycling became more popular in London, media coverage of fatalities increased from very few to almost all (while coverage of motorcycle deaths remained at the same very low level), despite no increase in the fatality rate itself. In Great Britain, fatality and injury rates for walking and cycling are very similar, contrary to public perception.

Fear of injury is a major deterrent to active travel and to parents allowing children to travel independently. Fear of “stranger danger” is also cited often. In the United Kingdom, the child abduction rate (which is tiny) has not changed in 50 years, only the extent of media coverage. Furthermore, few cases are perpetrated by strangers; most are family members or otherwise known to the family.

Community Severance

Barrier Effect

“Transport-related community severance is the variable and cumulative negative impact of the presence of transport infrastructure or motorised traffic on the perceptions, behavior, and well-being of people who use the surrounding areas or need to make trips along or across that infrastructure or traffic” (Mindell et al., 2017). Community severance, also known as the barrier effect of busy roads or of transport infrastructure, has a wide range of effects on how and whether people travel and thus on factors affecting health (Fig. 2). A recent estimate in the UK puts the costs of community severance, from journeys not made, money not spent in local businesses, and health consequences of reduced social networks, at around 3% of GDP, similar to the societal costs of road traffic collisions in most countries. Although car users spend more on average in a single trip, they visit local businesses less frequently than other people. Over a period of time, people traveling on foot, by cycle or by public transport spend more in local businesses than individuals traveling by car.

Social Networks

Community severance was first described by Appleyard and Lintell (1972), in their ground-breaking study of San Francisco streets. They found that the heavier the traffic, the fewer the number of friends and acquaintances residents had among the neighbors in their

Figure 2 Theoretical model for the health effects of community severance. Source: *Mindell and Karlsen (2012)*

street. They also found that traffic reduced the use of streets as social places to meet, chat, and play, and restricted people's views of their "home territory."

This is important because having an extensive network of social contacts, including nodding acquaintances, has a major impact on health. People with more social contacts are healthier, have fewer hospital admissions, and are less likely to die prematurely. The effects are large, being of similar magnitude to the benefits of stopping smoking (*Holt-Lunstad et al., 2010*).

Pedestrian Crossings

One of the major impacts of community severance is in impeding road crossing. The number, type and location of crossings can affect this considerably. It is particularly a problem for people who walk slowly, due to childhood or old age; have a mobility impairment (whether acute, such as a broken leg, or chronic); have luggage or wheeled baby buggy; or are accompanying children.

Pelican crossings assume a walking speed of at least 1.2 ms^{-1} during the "clearance" time (that allows those who have already started to cross to reach the other side of the road before the motor vehicles resume). However, numerous studies have found that older people, for example, walk much more slowly than this. Typical values are mean walking speeds of 0.9 ms^{-1} for men and 0.8 ms^{-1} for women aged 65 + years (*Asher et al., 2012*). Newer countdown crossings, that give exact information about the time remaining to complete the crossing, and Puffin crossings, that use cameras to keep the signals red for motor traffic while a pedestrian is still crossing, are better solutions. Unsignalised pedestrian "Zebra" crossings can also be a solution, but only where drivers actually stop.

Table 1 Summary of inequalities in transport modes and health

<i>Population group</i>	<i>Health effects of transport</i>					<i>Community severance</i>
	<i>Independence/dependence</i>	<i>Physical activity</i>	<i>Air pollution</i>	<i>Noise pollution</i>	<i>Injury</i>	
Children and adolescents	Limited options	Important but depends on permissions	More susceptible	More susceptible	More susceptible	More exposed
Older people	Limited options	More difficult	More susceptible	More susceptible	More susceptible	More exposed
Gender	Male > female	Cycling mostly male Walking more females			Male > female	Female > male
Sexual orientation	Potential for homophobic attacks on public transport					
Poverty	Limited options	Need to avoid excessively long journeys	More susceptible & more exposed	More susceptible & more exposed	More susceptible & more exposed	More exposed
Ethnicity	Maybe limited options		More exposed	More exposed	More susceptible & more exposed	More exposed
Poor health / impairments	Limited options		More susceptible & more exposed	More susceptible & more exposed	More susceptible	More exposed

Concern about their ability to cross the road safely can prevent older people and others from leaving home if their journey would entail crossing a busy road. This is important because both subjective feelings of loneliness and objective measures of isolation are associated with increased mortality.

Other Benefits of Active Transport

Independent Mobility

In children and youth, active travel to school and other destinations provides an opportunity for independent mobility, which further helps young people to develop their spatial processing skills and skills for navigating safely environments with traffic. Independent mobility and the freedom to play outdoors also enhances musculoskeletal development and self-esteem.

Cognition

Both physical activity and environmental stimulation can improve cognition, as well as well-being, in older people. A recent study demonstrated improved cognitive function in older people who took up cycling (on conventional or e-bikes) for at least half an hour at least three times a week. E-bike users also improved their processing speed (reaction times).

Improving Access

Active travel can also equitably improve access to education, employment, and healthcare. This is particularly important for disadvantaged groups and in areas where public transport is not available, not affordable, or not easily accessible.

Inequalities in Transport Modes and Health

Distribution of Impacts

The health effects described above are inequitably distributed within the population, due to a range of factors. In general, benefits accrue to wealthier car drivers, while adverse effects are experienced mostly by more deprived groups (Mindell et al., 2011a). Car-dependent societies increase inequalities as young people, those with impairments through disease or ageing, and those too poor to afford to own or run a car have difficulties accessing preferred destinations. Intersectionality is also important—some groups of the population have multiple disadvantages. This applies, for example, to those who are particularly vulnerable to adverse health consequences of climate change, which are likely to impact particularly on all the disadvantaged groups described below. **Table 1** summarizes inequalities in transport modes and health related to age, gender and sexuality, socioeconomic position, ethnicity, and impairments are provided in **Table 1**.

Age

Children and Adolescents

The benefits of independent mobility for self-esteem, musculoskeletal, and cognitive development have been mentioned. Without parental permission for active travel, young people are dependent on others to drive them or accompany them on public transport until they are old enough and have sufficient funds to use public transport alone.

Older People

As people age, sensory, cognitive and/or other impairments may lead to cessation of driving. Impairments also restrict the ability to walk or cycle—cycling (using adapted cycle, e.g., tricycle) may be possible when walking is not an option due to musculoskeletal or balance problems. Difficulties with wayfinding is an early symptom of dementia. Public transport can be difficult to use if pedestrian crossing facilities do not allow time to cross roads to access bus stops, and for people with difficulties with steps into buses or stairs at stations.

The injury consequences of collisions and falls are often more serious. In many high-income countries, hospital admissions due to falls when walking are more numerous than those due to collision with a vehicle. Pavements are often uneven, and those with slower reactions or poorer sight and balance will be at greater risk of falling. Even where there is a sidewalk, the quality of the surface may be poor. Falls lead to a loss of confidence and further self-imposed constraints on independent mobility. Dependency on others for transport also leads to loss of self-esteem. Travel difficulties are a cause of social isolation, particularly among older people.

Gender and Sexuality

In many countries, men are more likely than women to hold a driver's licence, to own a car, and to have use of a car where there are more adults than cars in a household. Thus the benefits of driving accrue more to men and the health harms from other people's cars are felt more by women.

There is increasing evidence of sexual harassment on public transport and in the street in many high- and low-income countries. This is predominantly targeted at women in general but can also have a homophobic origin. Such harassment is unpleasant, affects mental well-being, and is a deterrent for travel; it can lead to assault with injury, or even rape or death.

Socioeconomic Position

There are health and inequalities impacts of spatial planning that assumes car use. Car ownership and use is generally expensive but may be necessary, particularly in rural areas without other options (or in cities with no provision except for cars). Injury risk is higher for those living in deprived areas, and is more likely to occur in more deprived locations. Poorer areas may not have public transport or it may be unaffordable. In low income countries and in informal settlements, women may walk 2 hrs each way to employment because no public transport or need to choose between bus fare and food. The adverse mental and physical health effects of inappropriately long journeys outweigh the benefits of this degree of physical activity.

Ethnicity

In many countries, members of minority ethnic groups are poorer than average. Some groups have lower educational attainment; even among those with good education, discrimination often leads to lower level, less well-paid jobs for the same qualifications. Thus, minority ethnic groups often have the same health inequalities as are caused by poorer socioeconomic position. In addition, discrimination or racism can affect people's willingness to use different travel modes. Refugees and other immigrants can experience problems with wayfinding or managing public transport systems due to language problems.

Impairments

Almost any type of disease or medical condition can affect a person's ability to travel or their choice of travel mode(s). Difficulties traveling result in loss of the health benefits of access to employment, education, goods, services, and people. Restrictions on travel mode options can be expensive, particularly if taxis or accompanying persons are required. This can lead to journeys not made, with loss of those benefits, or reduced expenditure on other aspects of life important for health. Impairment refers to a loss or lack of function or ability. Disability is socially defined, when a person with an impairment is restricted in what they want to do by the social, cultural, fiscal and built environment in which they live. People with visual impairment cannot drive or cycle (except on the back of a tandem) but can often walk or use public transport, although they may need aids such as a guide dog or a white stick. Shared spaces can be treacherous, particularly if the curb is removed. However, dropped curbs are important for wheelchair users and others with encumbrances such as buggies or luggage, or who cannot manage steps. Individuals with impaired hearing may find wayfinding harder, if directions or public transport information is aural not visual, and may not hear approaching vehicles, whether motorized or cycles.

Musculoskeletal, cardiovascular, and neurological conditions can restrict the ability to walk or cycle. Cardiovascular and neurological conditions may prevent driving. Restrictions are stricter for professional drivers, who may lose their livelihood following a stroke, heart attack, or epileptic fit.

Mental illnesses also impact on the ability to travel. These impacts relate to difficulties managing the travel mode (e.g. wayfinding, understanding timetables or ticket machines); attitudes and/or behavior of bystanders or other travelers; and expense. Train tickets bought on the day are often much more expensive than tickets bought in advance. People with a fluctuating illness cannot know in advance whether or not they will be able to travel on a given day. Anxiety and depression are common conditions; agoraphobia, claustrophobia, or suffering from panic attacks can also impede travel (Mackett, 2019).

Dementia-friendly cities aim to improve wayfinding for people with cognitive loss. People with learning disability can learn to commute unaided but it takes more time to develop and retain these skills. However, despite the expense of providing trainers, it is very important as employment is a major source of self-esteem that improves mental health.

The Future

When considering health impacts of travel and choice of travel mode, it is always important to specify the alternative. For example, if traveling by private car, electric power will impose fewer negative health consequences on the surrounding population than use of fossil fuel. However, each causes more adverse health impacts for the users and for the population than active travel as an alternative to car use. Autonomous vehicles may improve access for those with limited travel mode options, or those dependent on others to drive, bringing benefits of greater access and reduced isolation. Autonomous vehicles may also reduce the risks of injury while reducing congestion. Shared use rather than private ownership would reduce the number of vehicles and the amount of parking needed, releasing more space for more social uses. However, if shared use schemes are used primarily by those who would otherwise walk or cycle, the overall health impacts will probably be negative.

Summary and Conclusion

Transport has many benefits and harms for health. Benefits include access to education, employment, goods, services, and people as well as opportunities for physical activity and for being in green or blue spaces. Health conditions and illness can restrict travel mode options, reducing the health benefits of travel. Transport-related harms include air and noise pollution and greenhouse gases, sedentary lifestyles, injuries, and community severance. Active modes of transport, such as walking and cycling, contribute to increasing or maintaining physical activity, maintenance of healthy body weight, and better mental and physical health overall. Most public transport journeys involve some active travel. However, in car-dominated societies, adverse effects of transport are experienced mostly by more deprived communities whereas benefits generally accrue to wealthier car users.

Biographies

Professor Mindell is a Public Health Physician. She leads the Health Survey for England team and is the Health lead for UCL's Transport Institute. She conducts research into community severance (the barrier effect of busy roads and transport infrastructure) and also publishes on road fatality rates. She was lead editor of the 2011 report *Health on the Move2*. She is founding Editor-in-chief of the award-winning *Journal of Transport and Health* and is a member of the Executive of the Transport and Health Science Group (founding its Latin American network) and of the International Professional Association for Transport and Health.

Associate Professor Sandra Mandic is an Exercise Scientist. She leads interdisciplinary and multi-sector research projects in physical activity and health in New Zealand with the links to transportation, built environment and sustainability. Her academic training and professional experiences span Europe, Canada, the United States, and New Zealand. She is the academic leader of the Active Living Laboratory, the principal investigator on the Built Environment and Active Transport to School: BEATS Research Programme and the convener of the Transport Research Network at the University of Otago, New Zealand.

Introduction: Different Notions of Multimodality

In recent years, the most prevalent use of the term multimodality in transportation referred to the (flexible) use of different transport modes. Within the automobile-oriented societies of the Global North, this notion of multimodality has been postulated as an ecologically sustainable alternative to the exclusive use of private cars since the 1990s at the latest. This is part of general efforts to reduce the use of the car, which is less resource-efficient than alternative modes of ground transportation, specifically when powered with fossil fuels. Multimodal behavior has been observed to go along with less car use and less vehicle-kilometer traveled (VKT) than monomodal car use in everyday travel (Nobis, 2007). Hence, much attention has been paid to multimodality, additionally fueled by the increase in multimodal behaviors among the millennial generation, that is, the generation of young adults born in the period from the early 1980s to the mid-1990s. Compared to previous generations of young adults, millennials exhibited a decline in car ownership and use, suggesting a shift away from the automobile toward more multimodal behavior patterns (Kuhnimhof et al., 2011; 2012) (detailed contribution about Next Generation Travel by Kuhnimhof and Levine, 10429).

While this behavioral dimension of multimodality has mostly been in the focus of transport research, the term multimodality can also be applied to the supply side of the transport system or to summarize a specific set of transport policy strategies.

Multimodality as a Property of the Transport System

On the side of transport supply, multimodality is a property of a transport system that provides travelers with the material option of using different transport modes. Put more generally, a multimodal transport system comprises a nonmonolithic composition of all structural components, that is, the entire set of external and internal mobility resources and the corresponding rules, that enable the movement of people or goods by different transport modes (see e.g., Spickermann et al., 2014). A conventional example in this context is a multimodal corridor which provides travelers with various options to travel from A to B. Key examples for likely increasing multimodality of current transport systems are represented by the dynamic developments in the field of smart mobility based on interconnected mobility services (car sharing, bike sharing, scooter sharing, etc.). These are based on the principle of usership instead of ownership, thereby substantially decreasing the fixed costs while increasing the out-of-pocket costs of using a

specific transport mode. This—in connection with the flexibility of modern ICT—facilitates situationally flexible mode usage and hence fosters multimodal behaviors (detailed contribution about ICT and Transport Modes by Cohen-Blankshtain, 10422).

Multimodality as a Facet of Individual Travel Behavior

On the side of travel demand or travel behavior, multimodality on the level of an individual traveler is defined as the use of more than one mode of transport over the course of time. The prevalence of multimodal behaviors within a society is also an indicator describing the multimodal quality of transport systems and hence the underlying transport policy strategies. By comparing different countries of the Global North, substantial differences can be identified in this regard. For example, representative studies show that multimodal behaviors tend to be less pronounced in North American countries due to strong car centrality (Buehler and Hamre, 2015) than in European countries such as the United Kingdom (Heinen and Chatterjee, 2015), Germany (Nobis, 2007), the Netherlands (Krygsman and Dijst, 2001), or Denmark (Olafsson et al., 2016). However, measurement methods used to quantify multimodal behaviors often vary between the studies, so they do not allow a direct comparison of the prevalence of multimodal behaviors.

Multimodality as a Transport Policy Strategy

Finally, multimodality may also be a transport policy strategy seeking to improve the multimodal qualities of a transport system, hence aiming at increasing multimodal travel behavior and thus achieving more sustainability in the transport sector (e.g., Chlond, 2012; Dacko and Spalteholz, 2014). Such strategies aim at promoting the integration of transport modes through different channels in order to achieve a better utilization of the multimodal supply. This is currently being pursued at various (political) levels. One example is the proclamation of the “Year of Multimodality” for 2018 at the level of the European Union in order to reduce local pollutant and global greenhouse gas emission problems within the EU states and thus to improve the quality of life of the people in accordance with the Paris Agreement. Likewise, states, metropolitan regions, cities, or companies meanwhile have their own strategies to promote multimodal behaviors within their institutions. Unlike other policies to achieve increased sustainability of the transport sector, such as policies to ban cars from city centers, multimodality carries the notion that each transport mode – including the car – fulfills an important function in the transport system. Hence, multimodality as a policy strategy often works as a common denominator across very different stakeholders including automobile advocates and can help building bridges in controversial mobility discourses (Block-Schachter, 2009).

The structure of the paper is as follows: Section [Terminological Heterogeneity in Research on Multimodality](#) presents the existing terminological variety in research on multimodality. Section [Measurements of Multimodality](#) describes different approaches to measuring multimodal behaviors. In Section [Reasons and Causes for Multimodal Behaviors](#), observed causes and reasons for multimodal behaviors are outlined. Then, Section [Smart Mobility based on Interconnected Mobility Services: New developments in Multimodality?](#) sketches emergences in interconnected mobility services, which are associated with increased multimodal behaviors. Finally, a critical conclusion is drawn on the current role of multimodality as an alternative to the private car.

Terminological Heterogeneity in Research on Multimodality

In addition to the different concepts of multimodality as discussed earlier there exists a complex variety of further contrasting, complementary and delimiting terms, which are epistemologically relevant for research or practically relevant for planning:

Contrasting Terminologies

Multimodality is contrasted mainly with monomodality: While multimodal behaviors are described by the (flexible) use of more than one transport mode, monomodal behaviors are characterized by the use of only one mode in a certain time period. These two contrasting concepts play a role within research on everyday mobility in at least two respects: First, in the context of the debate on a possible transition from an automobile to a multimodal society, according to which multimodal behavior is understood as a sustainable alternative to monomodal (“nonsustainable”) car use (e.g., Chlond, 2012; Nobis, 2007). Second, considering the restrictive effects of transport poverty, according to which socially marginalized persons (low income, formally low education, precarious employment, etc.) are often excluded from access to multimodal behaviors due to a lack of mobility resources, and thus practice more often monomodal behaviors (e.g., Blumenberg and Pierce, 2014).

Supplementary Terminologies

In most studies, multimodality is further differentiated in terms of the respective research interests. A prominent example is the use of the terms bimodality, trimodality, etc., to express the additional modes used (e.g., Klinger, 2017). In another example, researchers distinguish between the environmentally sustainable quality of combined transport modes, for example, with regard to “green multimodal behaviors” (i.e., the combination of active and public modes) on the one hand and “car-based multimodal behaviors” (i.e., the use of at least one other mode besides the private car) on the other (e.g., Hunecke et al., 2020; Mehdi-zadeh et al., 2019).

Another emphasis is on modality styles, according to which habitual combinations of transport modes are examined in combination with individual life situations and/or specific psychological values and attitudes. In this respect, [Vij et al. \(2013\)](#), for example, identify three segments of different Modality Styles using economic parameters from German data: (1) "Habitual drivers," who view the world from the steering wheel and imagine distances in terms of driving times and locations in terms of available parking spaces; (2) "Time sensitive multimodals," who switch between many different travel modes, but make a trade-off between the different modes and the estimated travel time; and (3) "Time insensitive multimodals," who flexibly choose their transport options based on other criteria than travel time. Likewise, the segments of [Diana and Mokhtarian \(2009\)](#), which include subjective evaluations of modes and desires to change modes in addition to objective mode use, can be cited. For a French data set they distinguish (1) "Very light travelers, monomodal car users, deprived re other modes," (2) "Light travelers, car dominated but multimodal, deprived re other modes," (3) "Moderate travelers, highly multimodal, mixed satisfaction," und (4) "Heavy travelers, highly multimodal, generally surfeited."

Delimiting Terminologies

Within this conceptual heterogeneity of multimodality, we would like to point at three additional distinct concepts, which are related to the concept of multimodality, but represent independent fields of research and practice:

1. Intermodality describes the interlinking of different transport modes on a single trip. The term originates from freight transport, according to which containers are moved "inter modes," that is, between the transport modes ([Donovan, 2000](#)). In everyday mobility, intermodality plays a role at certain intermodal transfer points, for example, mobility hubs, park-and-ride parking spaces or bike-and-ride spots in public transportation. At the level of regional transport planning, the expansion of such intermodal hubs is considered important, since the opportunities for intermodal travel outside urban areas are limited (e.g., [Oostendorp et al., 2019](#)). In some studies (especially from the Anglo-American context) the term intermodality is often used synonymously with the term multimodality. However, both from a scientific point of view and in planning practice, the inconsistent use of the terms can lead to confusing ambiguities.
2. Intramodality describes the synchronous movement of transport modes along a single trip. Intramodality is practiced, for example, where transport modes may be carried within transport modes. A progressive initiative to promote intramodal transportation is, for example, the possibility to carry a bicycle on public transportation.
3. Multioptionality, which is used primarily in German-language transport and mobility research, shifts the perspective from actual mode choice toward potential mode choice ([Groth, 2019](#)). The concept of multioptionality was introduced to acknowledge the fact that the opportunities for participating in multimodal behaviors are unequally distributed in societies (i.e., "not everyone can be a multimodal"). A distinction can be made between material and mental multioptionality; material multioptionality describes individual access to more than one mode option based on available mobility resources (e.g., driving license and car availability + available bicycle). Mental multioptionality describes individual receptiveness to the use of more than one transport resource (e.g., based on the subjective evaluation processes of individual transport resources).

Measurements of Multimodality

There is a broad variety of multimodal segmentations and part of this heterogeneity is based on different methodological approaches. Typically, the analysis of multimodal behaviors is based on quantitative methods although there are also a few qualitative approaches (e.g., [McLaren, 2016](#)). Among the quantitative approaches, at least four factors can be identified which influence segmentation and vary across studies on multimodality and hence lead to varying proportions of different multimodal groups within the population of travelers: (1) Length of reference or observation period for which transport mode use is captured, (2) methods of capturing transport mode use, (3) types of transport modes to be considered, and (4) intensities of mode variability within the observation period:

Methods of Capturing Transport Mode Use

The conventional method of capturing multimodal behaviors are travel diaries in which survey participants record individual trips during a defined observation period (e.g., 24 hours or 7 days) including relevant trip properties such as the transport mode used. Travel diary surveys are well established since decades and relatively comparable in format across different countries and over time. With the emergence of GPS-tracking as an element of travel surveys there is additional precision and granularity with regard to capturing mode use, for example, it has become easier to capture the use of multiple modes for a single trip ([Kuhnimhof et al. 2018](#)). An alternative to capturing mode use for single trips are survey items inquiring about the typical mode use of individuals. For example, travel surveys may include questions about how often people typically use specific modes with response categories such as "daily," "on one to three times per week" etc. ([von Behren et al. 2018](#)). The use of multiple modes and hence multimodality during a given period of time can hence also be established with such survey items capturing typical mode use. [Nobis \(2015\)](#) found that the findings on multimodality based on such typical mode use questions compare by and large to the results based on trip diary surveys.

Reference or Observation Periods

During any given single day, most travelers use one or few modes only, that is, many are monomodal during short periods of time. During an entire year, however, most travelers use a broad variety of modes and are multimodal. Hence, the longer the reference period for capturing multimodal behaviors, the larger the proportion of multimodal groups as opposed to monomodal groups. Against this background, different reference periods are chosen across the studies, depending on the respective research questions: A reference period of several weeks is suitable, for example, to identify deep-seated mode use habits, within the framework of the above-mentioned Modality Styles (e.g., [Vij et al., 2013](#)). However, a one-week observation period is chosen in most studies to record multimodal behaviors, since during this period cultural processes are cyclically repeated in western societies and the typical variability of mode use can be depicted on this basis (e.g., [Buehler and Hamre, 2015](#)). Also, observation periods of a few days are used. Particularly when project budgets do not allow for extensive travel diaries, just a few days can be observed and still provide helpful indications of different behavior patterns of different social groups (see e.g., [Hunecke et al., 2020](#)).

Types of Transport Modes

With regard to the mode types the following pattern applies: The more types of modes are considered for establishing multimodal behaviors, the larger the share of multimodal groups. In most cases, therefore, only the use of the four main transport modes is recorded, that is, (1) car (as driver), (2) public transportation, (3) bicycle, and (4) Walking. However, some studies emphasize the importance of including as many modes as possible (e.g., car use as passenger, motorcycle use, taxi use, car sharing) (e.g., [Diana and Mokhtarian, 2009](#)). Some others focus on multimodal behavior in the context of a reduced choice of transport modes; for example, [Diana \(2012\)](#), who conducts his multimodality study exclusively involving car and public transport. Sometimes specific transport modes are also grouped together, such as trains, trams and buses for public transportation or cycling and walking for active transportation (e.g., [Heinen and Chatterjee, 2015](#)). With regard to the transport modes to be included in the segmentation process, the need to consider walking is debatable. Each trip begins on feet (i.e., also accessing the car or the train). Therefore, it is not always possible to draw a clear line from which point onward walking should be included as an independent type of transport. Some studies therefore do not include walking.

Variability of Mode Use

Consider the case of two individuals A and B who both use the car and the bicycle during the course of one week. While individual A switches between car and bicycle for the work commute every other day, individual B exclusively uses the car from Monday to Saturday and undertakes a single cycling tour on Sunday. This example visualizes how multimodality can vary in intensity even though both individuals could be equally considered “bimodal.” The intensity of multimodal behaviors hence varies interindividually and can therefore be of importance for a specific research interest. As the example above illustrated, categorical approaches often prove to be insufficient. Some studies that carry out segmentation emphasize proportions of the use of transport modes in order not to overemphasize modes that are rarely used. The best-known distinction between a “multimodal core” and a “multimodal tendency” is provided by [Nobis \(2007\)](#): Only those travelers belong to the multimodal core for whom there is no dominant transport mode; that is, no mode with which they cover over 70% or their trips. With regard to the goal of precisely mapping mode variabilities, however, such categorical approaches are sometimes criticized as heuristic. Alternatively, the methodological application of various indices has been established, originating from welfare economics (e.g., Gini, Dalton and Atkinson indices) or from information theory and ecology (e.g., entropy, Herfindahl-Hirsch index). [Diana and Pirra \(2016\)](#) offer a comprehensive portrait of possible index approaches for measuring multimodality, which in turn have different strengths and weaknesses with regard to specific research questions.

Reasons and Causes for Multimodal Behaviors

The literature on multimodality identifies four classes of factors, which appear to explain individual multimodal behaviors: (1) Availability of mobility resources, (2) settlement structures, (3) sociodemographic, and (4) psychologic characteristics. Among these classes there are factors that facilitate and other that impede multimodal behaviors ([Table 1](#)):

Mobility Resources

Almost all studies on multimodality report similar patterns with regard to the impact of specific mobility resources on travel behavior. For example, studies almost unanimously agree that car-related mobility resources—that is driving license, car availability, car ownership, and an increasing number of cars in the household—bear a strongly negative relationship with multimodality. In contrast to car-related mobility resources, the availability of mobility resources for alternative transport modes to the car (e.g., public transport season tickets or bicycle availability) can be placed in a positive relationship with multimodality. This finding confirms the everyday experience that—in automobile oriented societies—the car is a universal mode of transport enabling a (monomodal) modality style while the alternatives (public and active transportation) need to be combined to satisfy the broad set everyday mobility needs.

Table 1 Beneficial factors and barriers for multimodal behaviors

<i>Determinants</i>	<i>References</i>	<i>Beneficial factors (+) / barriers (-) for multimodality</i>
Mobility resources

Settlement Structures

With regard to settlement structures as an explanatory variable, in particular density and land use have been identified as relevant:

First, multimodality studies usually establish connections between multimodality and high population density. On the one hand, there is an explanation that links to the availability of mobility resources as set out above. Public transport and mobility services tend to preferably serve high-density areas as these promise high utilization of the services. On the contrary, sparsely populated suburban and rural areas often do not offer comparable alternatives to the car. On the other hand, car ownership and use in high-density areas is often associated with higher cost (e.g., for parking) or more hassle (e.g., searching for parking) than in less densely populated areas. This factor also restricts car use and gives rise to multimodal behavior.

Second, multimodality studies discover a connection between multifunctional settlement structures and the flexible use of alternatives to the private car. However, since monofunctional and disperse settlement structures are a reality in many instances, the bicycle, for example, represents a typical component of a multimodal transport choice set. It is rarely suitable for reaching all destinations and is therefore combined with other transport modes.

It should be critically noted that the interactions between space and specific travel behavior are much more complex. While settlement-structures clearly correlate with travel behavior, it is unclear, to which degree settlement-structures determine travel behavior or are linked to travel behavior in some other way, for example, through residential self-selection (see contribution, e.g., by van Wee about transportation and space, 10404).

Sociodemographic Factors

Sociodemographic factors are most frequently used to provide explanations for multimodal behaviors. However, it turns out that the individual variables can rarely be considered independently. Two examples of the relationship between sociodemographic variables and multimodal behaviors can be highlighted (see others in the table): First, in the datasets of European countries, women are more often associated with multimodality, while men more often show monomodal car use. In North America it is the opposite. In both cultural contexts, the differences are explained by the researchers as a result of the reproduction of traditional role relationships, according to which women are still more often involved in traditional household commitments, which in turn entails heterogeneous interrelationships of travel. While in the American context the average number of cars per household is higher, European households often have fewer cars available, which in turn tend to be used more often by men (see e.g., [Buehler and Hamre 2015](#); [Heinen and Chatterjee 2015](#)). However, among the generation of young adults there is evidence of equalization of gender differences due to similar life situations (e.g., [Kuhnimhof et al. 2012](#)).

Second, income seems to play an important role with regard to the material preconditions for the realization of multimodal behavior. In this respect, it is assumed that with rising income, the mode options for implementing multimodal behaviors also increase ([Heinen and Mattioli 2017](#)). By contrast, low-income groups are associated with a lack of mobility resources, which makes multimodal behaviors more difficult (e.g., [Blumenberg and Pierce 2014](#)). However, social status has to be taken into account here as well: For example, socially marginalized groups (low income, formally low education in precarious employment, etc.) are particularly affected by transport poverty and have problems in implementing multimodal behaviors, whereas students—who may also have a low income—often benefit from having access to multimodal services (In Germany, e.g., students receive the semester ticket as a low-cost season ticket for public transport) (see also contribution by Mullen about transport modes and inequalities, 10604).

Psychographic Characteristics

The explanations of multimodal behaviors by means of the psychographic characteristics of the traveler are versatile and refer to different psychological dimensions. Three examples:

First, positive and negative attitudes toward the use of different transport modes can correspond to the equivalent combinations of transport modes. For example, [Molin et al. \(2016\)](#) can link the monomodal use of private cars to positive attitudes toward the car and negative attitudes toward the use of public and active transportation. However, they also show that positive attitudes toward the use of modes do not necessarily coincide with the use of transport. This is particularly true for socially marginalized groups (low income, precarious employment, etc.) whose use of transport is more strongly determined by socioeconomic restrictions.

Second, multimodal behaviors can be directly linked to symbolic-emotional evaluations of transport modes. For example, the debate on the transition from the automobile toward a multimodal society is directly linked to the assumption that an emotional departure from the private automobile is taking place within the generation of young adults. However, some initial studies suggest that this is predominantly a milieu specific phenomenon among cosmopolitan intellectual circles (e.g., [Hunecke et al., 2020](#)).

Third, (dis)satisfaction with the use of specific transport modes can be identified and used to make improvements in the structural moments of transport systems. [Diana \(2012\)](#), for example, surveys multimodal car and public transport travelers to get indications on how public transport could be improved to replace car trips by public transport trips.

Smart Mobility Based on Interconnected Mobility Services: New Developments in Multimodality?

The way in which multimodality could be examined in the future is changing with the possible transition toward smart mobility based on interconnected mobility services. Smart mobility is a complex socio-technical composition, whose contours are still emerging. [Figure 1](#) shows two key elements that contribute to a better understanding of how multimodal behaviors work in the context of Smart Mobility: The first crucial key element of smart mobility relates to the increasing options of replacing vehicle “ownership” by vehicle “usership.” In addition to the “traditional” public services (mainly rail, tram, and bus), which are related to services of general interest, there are now also services in business-to-consumer (B2C) or peer-to-peer (P2P) format. B2C services are rental services, in which “users” appear as renters of transport modes offered by the service provider (e.g., station-based and flexible car sharing, bike sharing, scooter sharing). In the case of P2P services, the service providers act as intermediaries in the background, whereby their service consists in matching the providers and demanders of a mobility resource (e.g., carpooling, private car sharing, noncommercial open-source approaches) (see more the detailed contribution about Shared Mobility by Shaheen and Cohen, 10420).

Figure 1 Multioptionality/potential multimodal behaviors based on smart mobility/interconnected mobility services (Similarly published in Groth, 2019).

The second key element of multimodal behaviors based on emerging smart mobility refers to the connectivity of all mobility services. The emergence of smart mobility based on interconnected mobility services today implies a decisive evolutionary step, rooted in the fusion of the virtual world and the physical-material world (see also the more detailed contribution about Mobility as a Service by Mladenovic, 10607). From the user's point of view, modern information and communication technologies allow the user to always flexibly and situationally choose the appropriate transport mode. The smartphone can be seen as the core of multimodal behavior based on smart mobility. For example, smartphone applications are used to obtain real-time information on arrival and departure times or to find available community vehicles. In addition, these apps enable users to buy tickets or reserve a vehicle. Finally, the smartphone guides the way to the station or available vehicle via GPS and serves as a key to open the vehicle lock.

Conclusions

Without doubt, multimodality is one of the major relevant issues in the field of modern everyday mobility and promoting multimodality is a wide-spread paradigm to increase environmental sustainability of transport. However, it should be kept in mind that more multimodality does not always increase environmental sustainability as clarified by the example of a monomodal cyclist who turns multimodal through conducting more trips by car. Hence, multimodality—even though it is often treated as such—is not a

value in itself independent from circumstances. Instead, environmental benefits can only be gained if multimodal behavior replaces behavior that previously was more automobile centered. But even under these circumstances, however, both academic research and transport policy practice cannot automatically conceptualize multimodality as a sustainable alternative to the private car. Three examples:

1. The often emphasized idealization of minor segments of society as drivers of transition processes (e.g. changed mobility in cities or more multimodality among young adults) runs the risk of overlooking the reproduction of dominant automobility. As a consequence, socially and spatially selective trends are being stylized into ubiquitous trends, without further forcing the shift away from the private automobile in terms of transport policy. Consequently, it is important in research to keep the big picture in mind and to examine in detail in which contexts automobility as a hegemonic transport system is actually being replaced and in which it is not.
2. As for the climate impact of passenger transport long distance travel is about as relevant as urban travel. This also extends the view to the boom of global air traffic that has been experienced in recent years. As is known, air travel—facilitating long distances and currently completely dependent on fossil fuels—is at least as worrisome as automobile travel as for its climate impact. However, by nature air travel is intermodal and airports act as intermodal interfaces on transregional travel, whereby passengers use traditional and/or new mobility services after their flights at the departure and destination airports to complete their intermodal route chain. New and traditional mobility service providers enter into new alliances with airlines. Hence, intermodality and multimodality may also be associated with increasing air travel, for example, if those urban dwellers without car more often opt for air travel in the case of long-distance travel. Hence, the concept and analysis of multimodality should not be limited to urban travel but include all relevant facets of travel in order to obtain a comprehensible picture (see, e.g., contribution on geographies of air transport by Lucy Budd and Stephen Ison, 10426).
3. Finally, a dichotomous focus on automobility versus multimodality at the urban-regional level may lead to the neglect of potentially sustainable monomodal transport concepts at the transport policy level. However, in a few countries, such as the Netherlands, bicycle cities have been successfully realized in the last decades, which represent an ecologically sustainable urban transport beyond automobility and multimodality (see detailed contribution about car-free cities by Khreis, 10707).

The methodological and analytical approaches presented in the previous sections help to keep a critical eye on the research on the concept of multimodality and to enrich the discussion on the concept with new observations. Furthermore, from the perspective of transport policy and planning practice, it should always be carefully examined to what extent multimodality can contribute to socially and ecologically sustainable everyday mobility on the ground.

Introduction

Transportation and the roles that it plays during disasters are as varied as they are complex. A long history of experience has illustrated the vital functions they play in all phases of emergencies, before, during, and after they occur. In addition, to providing the modes and paths to evacuate people prior to the arrival of a hazard, transportation assets are also vital to prepare and preposition supplies before dangers arrive. During and immediately after a disaster, transportation modes and systems support numerous aspects of disaster response from search and rescue, to transporting the injured, to fighting fires and so forth. Then, after a disaster, transportation supports recovery, both immediate and long term, through the resupply of basic life-sustaining food, medicine, and building materials as well as serving as the conduits of re-entry for the return and re-entry of effected populations back into impacted areas.

Unfortunately, transportation can also become the source of disasters. Airliner crashes, ship sinkings, bridge collapses, and train derailments are a few of many examples of ways in which transportation modes and infrastructure have, themselves, become the source of injuries, loss of life, and damage to property and the environment.

In this entry of the *Encyclopedia of Transportation*, ways in which transportation has been used to prepare for, respond to, and recover from disasters as well as the ways in which it contributes to their occurrence of discussed. In particular, the discussion highlights how important features and characteristics and operational techniques of transportation can and have been be used to counter the detrimental effects of disasters. It also includes a brief summary of the evolution of transportation and its involvement and impact in events and hazards as well as the manner in which different transportation modes have and can be used in times of emergency. From an application standpoint the entry also includes a brief high-level discussion of various operational strategies and approaches to counter the effects of disasters and major events. Then, this entry summarizes recent emerging knowledge and examples of some disaster experiences to discuss the roles played by transportation in them and, conversely, how functionality was impacted.

Background and Fundamentals

While complex, the roles and involvement of transportation in disasters can also be described and analyzed in terms of the spatial and temporal characteristics of any specific hazard; most notably, how big of an area they impact, how long do their effects last, and how much warning time do they give to prepare, react, and respond. For example, some hazards, like hurricanes, impact thousands, if not tens of thousands, of square miles for hours or even days at a time. However, their arrival can be forecasted several days in advance. This gives time for protective action responses regional mass evacuations to be ordered and carried out to move hundreds of thousands of people over tens, if not hundreds, of miles. On the opposite end of this spatio-temporal spectrum are hazards like fires and explosions. While they may give little advanced warning, they typically impact comparatively smaller areas, as such the roles played transportation become limited to response and recovery after the event.

Table 1 includes a list of significant hazards that have, historically, impact transportation modes and systems. Conversely, the impacts of these same hazards have also been lessened though the various means of transportation to people and material goods. Because the contribution of transportation can be impacted by the size, scale, and timing of a hazard as well as its cause the table also includes the sources of each hazard in terms it occurring naturally or some type of intentional and/or unintentional human action. Perhaps most important from a transportation planning and/or action perspective is whether it was expected or unexpected and its levels of threat. The final column describes each of the listed hazards in terms of whether are planned or unplanned and whether or not it would be considered to be an emergency. Not surprisingly, when dealing with disasters, nearly all of these would be considered to be "unplanned emergency events."

Table 1 Hazard, types, sources effecting transportation

<i>Hazard</i>	<i>Cause</i>	<i>Type (transportation perspective)</i>
Earthquakes	Nature	Unplanned/emergency
Floods (rain, snow, hurricanes, surge)	Natural	Unplanned/sometimes emergency
Hurricane/typhoon	Natural	Unplanned/emergency
Ice storms	Natural	Unplanned/sometimes emergency
Landslides	Natural	Unplanned/sometimes emergency

Another important consideration in applying transportation resources, personnel, assets, and systems for disasters understands how likely and often events might occur. One of the most significant and under-addressed, issues of transportation in emergencies and disasters is dealing with the budgetary challenges of low probability-high consequence disaster events. In practical fact, it can be difficult to prioritize resources for conditions that may occur once in a generation, if at all. While the threat of injury and lost lives and impact to infrastructure may be enormous in many of disaster scenarios shown in [Table 1](#), traditional cost–benefit analyses cannot always justify the significant expenditures to counter them. Whether the approach would be to construct new systems, such as the one billion dollar Inner Harbor Navigation Canal Lake Borgne Surge Barrier to block a storm surge from entering Lake Pontchartrain near New Orleans, or reconstruct existing infrastructure to resist failure, nearly all such efforts are costly. Implementing such plans is also further hindered by budgets that are already unable to meet long lists of routine needs.

To counter the challenges of justifying investment to counter low probability-high risk events, newer approaches are being employed to plan, design, operate, and maintain transportation infrastructure and modal assets with a greater consideration of disasters, emergency management, and disruptions of all types. At the broadest level, these philosophies are classified as “resilient engineering.” Emergency management is the field with the responsibility to reduce vulnerability by preparing communities to mitigate, prepare for, respond to, and recover from hazards—from major and minor. By definition, the use of innovative, flexible, adaptable, and cost effective means to achieve overlapping preparedness, response, and rapid recovery needs is the fundamental principles of resilience. Thus, many of the tools and techniques used in emergency management, including hazard/risk/vulnerability assessments, readiness drills and exercises, and interagency coordination, are now being adapted into resilience-oriented transportation.

Evolution of Emergency and Resilient Transportation

In the United States (US), “transportation,” including planning and operation for disaster and emergency recovery and restoration, is designated by the Department of Homeland Security as the first “Emergency Support Function” (ESF) in the National Response Framework (NRF). The NRF, created soon after the terrorist attacks of 2001, guides the US response in disasters and emergencies. ESF are categories used to group emergency preparedness and response capabilities based on their ability to provide support, resources, personnel, etc. to during times of need. Like most current approaches to emergency management, the NRF structure takes a “scalable, flexible, and adaptable perspective” approach to disaster preparedness. These have evolved to be the core principles of resilience-oriented transportation.

In terms of all the disruptive events that can impact or benefit from the involvement of transportation, disasters are the most extreme. In practical terms, transportation disruptions can range from a minor as a stalled vehicle blocking a travel lane, to as a large

as a multistate mass evacuation. Thus, disaster preparedness and responses that seeks to achieve certain fundamental goals, like maintaining full functionality, but that are scalable, flexible, and adaptable to any planned, unplanned, or hazardous condition provide the most cost effective returns on investment and are, thus, more sustainable and achievable over long time horizons. Thus, when discussing transportation in disasters it is also important to first fundamentally understand the nature of the disruption that effects a transportation system, including not only how large of an area they impact and how long their effects last, but also how hazardous they may be to people and property and how often they may occur.

Although the focus of this entry is oriented toward major, large-scale disruptions and disasters, the current perspectives on transportation planning and engineering for such conditions are focused on broader all-disruption conditions. Reviews of practice suggest that the focus of most of the roles for and involvement of transportation disasters is most commonly associated with extreme weather, including most notably, flooding, hurricanes, and winter storms. Often, these events are also framed within the context of the long-term trends of global climate change and sea-level rise. Not surprisingly, the transportation involvement in disasters is also a based on the threats, hazards, and disaster that are faced in an area that is earthquakes in California, volcanoes in Hawaii, and tsunamis in southern Asia. Clearly, security and terrorist threats are also areas of emphasis in transportation; most obviously in air transport, but also in term of specific location and event venues.

Historically in the US, emergency management began as civil defense to protect citizens from military attack. Transportation, particularly the network of federally funded highway was envisioned to move military equipment and personnel. Later, during the Cold War, many of these planned to be used as evacuation routes to support the movement of people out of urban areas. Later, as populations grew in southern coastal areas of the country these same routes were looked upon to serve in a similar capacity, but for hurricanes rather than invasions.

Following the September 11, 2001 terrorist attacks, the newly created Department of Homeland Security developed the National Incident Management System (NIMS) that, with other organizational goals, sought to coordinate the involvement the capabilities of diverse agencies, like transportation. Within the broad frameworks of NIMS and the national Incident Command System (ICS) specific responses can be coordinated and adapted to counter the conditions with any hazard, large or small.

Focusing on transportation specifically, departments of transportation is evolving toward resilience approaches to support response and deal with emergencies and disasters. As part of these resilience philosophies, even broader and more comprehensive “all disruption” approaches are now being used. Functional disruptions expand the traditional hazard-oriented perspectives to also include any event, planned or unplanned, intentional or accidental, natural or man-caused, and catastrophic to routinely occurring. The use of the term functional disruptions is far more than semantics, however. Like the use of all-hazard emergency approaches that promote flexibly apply planning, response, and recovery to adapt and apply a range of options from a broad framework, resilience-oriented management also relies on flexibility and scalability to address an even wider range of conditions.

Table 2 includes a small cross-section of disruptive events to show how the characteristics of each are likely to impact a community and its transportation systems. In keeping with the philosophy of resilience, the table spans spatially-large and -small events, that occur with and without advanced notice, and that occur often and infrequently. In addition, to revealing the varied

Table 2 Event characteristic and relationships to transportation systems

<i>Event</i>	<i>Planning</i>	<i>Advanced notice</i>	<i>Duration</i>	<i>Hazard</i>	<i>Impact area</i>	<i>Frequency</i>
Vehicle Crash	Unplan/some emergency	None	Minutes to Hours	Low	Local to several miles	Frequent
Concert/ Sporting Event	Planned	Months/Years	1+ Days	None	Several Miles	Seasonally Frequent
Playoff Sporting Event	Partially Unplanned	Days	Hours to Days	None	Several Miles	Occasional
Major One-time Events	Planned	Years	1+ Days/Weeks	None	Several Miles	Infrequent
Parades	Planned	Months/Years	Hours	Low (Planned Road Closure)	Few Miles	Occasional
High Security Events	Planned	Days to Weeks	Hours to Days	Low	Several Miles	Occasional
Snow/Ice Storm	Unplanned	Hours to Days	Hours to Days	Medium	Regional	Seasonal, varies by region
Wildfire	Unplan/Emerg.	Minutes to Days	Hours to Weeks	Medium to High	Regional	Seasonal, varies by region
Flooding	Unplan/some emergency	Hours to Days (Usually)	Hours to Weeks to Months	Varies - Low to High	Local to Regional to Multi-State	Frequently, varies widely
Hurricane Evacuation	Unplan/Emerg.	Days to Weeks	Days	High	Regional	Seasonal Infrequent
Hazmat Spill	Unplan/Emerg.	None	Hours	High	Several Miles	Infrequent
Bridge Collapse	Unplan/Emerg.	None	Months	High	Several Miles	Infrequent

nature of these events, the table also suggests commonalities of the event characteristics and opportunities of where transportation planning and operations for one of them may be spatially and/or temporally adapted for us in others.

The benefits of resilient planning goes beyond the ability to more effectively respond to and recover from disruptions. These approaches also use more innovative approaches that while effective are less costly and more importantly can also achieve multiple overlapping benefits that span a larger range potential disruptions and achieve it for a reduced costs. This also gives them a more justifiable as business-need under practical budgetary limitations. A recent review of state-level department of transportation (DOTD) in the US was conducted to determine the what types of disasters, emergencies and other disruptive conditions were focused-on in when integrating resilience into transportation planning, preparedness, design, operations, and maintenance.

Among the findings were that agencies tended to categorize resilience operations in terms of: (1) transport mode (highway, air, rail, maritime, etc.) and their associated roles, needs, and characteristics during periods of disruption and/or by (2) the type of disruption (natural hazard, incident, planned event, etc.) that had occurred or could be anticipated for a location or system. In terms of performance outcomes and metrics to assess the effectiveness of agencies tended to focus on:

- Safety, in various forms that included crash rate and frequency, fatalities, injuries, damage to property, etc.;
- Economics, including the reliability of funding to support resilience;
- Technology, including technologically-oriented data collection surveillance, and communications systems as well as “cyber” issues and data, more broadly; and
- People, including agency employees/staff, system users/travelers, and vulnerable populations.

As societies become more complex and activities become increasingly complex and, in some cases, more potentially hazardous and dangerous, newer and perhaps even more threatening hazards emerge. Natech disasters are events that involve a cascading series of disasters that typically start with natural disaster, like an earthquake or flood, that lead to the occurrence of technological disasters, like chemical spills explosions etc. One of the most significant was the tsunami-nuclear plant natech disaster in Fukushima, Japan. In that incident and earthquake trigger tsunami knocked out control systems on the nuclear power plant resulting in explosions, fires and radiological releases. From a transportation perspective, the tsunami flooded roads, damaged infrastructure, and blocked access with debris slowing the ability to conduct search and rescue operations and move people out of the area. Then, the ensuing contamination made parts of the affected area too hazardous to enter slowing the long-term rebuilding and recovery process.

Increasingly sophisticated transportation modes and systems can also be susceptible to failure. While they are designed with back-up systems and redundant safety features, there have been numerous examples of highway, air, maritime, and train incidents resulting in crashes, spills, explosions, and sinkings which have caused injury, loss of life, and damage to property and the environment. Autonomous control, requiring various levels of human input have also been linked to some of these incidents. Unfortunately, as more and more vehicles become increasingly machine controlled and transportation infrastructure and control systems rely on sophisticated means of communication and operation, the potential for intentional and unintentional disasters exists.

Some other areas worthy of mention that are not “traditional” disasters as they are commonly regarded, but nevertheless involve or impact transportation are have come to attention recently. One of these is the displacement of people and, in some cases, mass movements of entire populations due to war, famine, economics and, increasingly, climate-related causes. Such movement have often taken place on foot or by other vulnerable and illegal means of travel and involved crossing (and prohibition) of national borders. While this remains a complex problem and one in which transportation plays a secondary role it is an important issue and one in which transportation can play a role. Yet another deals with discouraging, restricting, and prohibiting travel and mobility. As seen in the worldwide COVID-19 pandemic of 2020, the implantation of travel restrictions and closure of activity generators significantly decreased all form of travel. While this has resulted in both positive (lowered rates of virus transmission, decreased congestion, delay, crashes, fuel consumption, and emissions) it has also resulted in significant impacts to commercial exchange, employment, and, surprisingly, increases in vehicle fatal crash rates.

Modes

All modes of transportation have roles to play in disasters. However, their effectiveness and impact as either a means of preparedness, recover, and response to a disaster or significant incident or as a contributing source of them has varied. From a wide use perspective, highway transportation is the most commonly used mode for disaster preparedness (evacuation) and recovery (resupply, restoration, and return/repopulation). However, airborne modes are used extensively for similar purposes, particularly when the location is remote, distant, difficult to access, and requires rapid arrival of critical supplies. Airborne modes may also become the sole means of transport into and out of inaccessible areas with damaged highway and rail routes such as may occur during floods and earthquakes. Even during the response period of a disaster, assets from drones to helicopters to heavy aircraft have been used for damage assessment, search and rescue, and wildfire suppression.

Similar to airborne modes, the use of waterborne transport modes have also been used extensively, especially in remote and difficult to access locations like islands. A distinct advantage of maritime modes is the enormous capacity to move cargo making them well-suited to recovery supply roles. Unfortunately, scale comes with the limitations on rapid movement. Between loading, travel, and off-loading, shipments by seas can often take days, if not weeks to arrive. It is also important to note that not every location has port facilities to accommodate every waterborne vessel. In some cases, a combination of water vessels is required and even water-to-air-to-land intermodal transfers. Water-based transportation modes have also varied widely in scale. In addition, to

sea going cargo vessels, military hospital ships have been used to supplement land-based medical care, during the September 11th terrorist attacks a spontaneously organized flotilla of ferry's was used to move evacuees area from the World Trade Towers, and small multiperson airboats and flat bottomed fishing boats are often used for search and rescue in flood-impacted urban areas impacted areas with floating debris.

Rail transport is another key mode in disaster preparedness, response, and recovery. While not used as extensively as other modes for immediate shipping of relief and recovery supplies, rail transport has been an integral part of preparedness, on both heavy and light passenger rail lines. While it has evolved over the years since Hurricane Katrina in 2005, Amtrak passenger rail has been a part of the New Orleans City Assisted Evacuation Plan (CAEP). In fact, the CAEP featured a multimodal transit approach to evacuation; utilizing regional transit busses to circulate in the city picking up evacuees and transferring them to the Amtrak passenger rail hub for transport out of the city.

Rail and bus transit service is planned for use in hurricane-threatened major US urban areas like Houston and New Orleans, particularly for transportation-limited populations like the carless, economically-disadvantaged, and persons with functional needs. Modes such as paratransit, taxis, kneeling and wheelchair-assist busses, and even mobile phone app ride-sharing services are part of mobility assistance plans. Then, ambulances, air medivac craft, and other forms of medically assisted transport have been used and are plan to transport hospital patients, the infirm, and frail elderly person before and after emergencies.

Operational Strategies and Approaches

Historically, transportation systems were largely regarded as passive actors in disaster preparedness, response, and recovery. Transportation agencies often supported first responders and emergency management; however, prior to the late 1990s and early 2000s, these could be described as peripheral and reactionary, rather than proactive. Despite the role served by transportation in the variety of conditions discussed throughout this entry, prior to the formally designated roles within the NRF, most transportation agencies felt their focus should be solely on their traditional responsibilities. To most agencies this meant maintaining transportation systems and assets in as close to a full function as possible at all times, including during disasters and emergencies.

This is not to suggest, however, that transportation had no role in prior disasters and emergencies. As primarily public agencies, departments often supported first responders and emergency management agency's many aspects of preparedness, response, and recovery. When adequate warning time was available transportation agencies commonly supplied personnel, equipment, and materials like barricades for road closures and permitted modal assets to be divert and schedules modified for emergency support. Even private road and bridge authorities would lift toll charges to permit freely flowing traffic. Then, after emergencies, transportation agencies was active in clearing debris, repairing damaged infrastructure like bridges, embankments, pavements, culverts, signal control systems, etc. that impacted the operation of their system. However, these were not viewed upon as core roles of transportation agencies, but rather supporting requests from other agencies who's primarily responsibility was emergency management and coordination.

In the US, the vital roles that could be played by transportation in emergencies became more evident in wake of events like the September 11th terrorist attacks, California wildfires, and catastrophic hurricanes of 2005. Required involvement from transportation agencies and personnel were further formalized by the NRF. These groups are valuable during times of emergency because, among other capabilities, they bring expert knowledge of transportation systems and assets under their jurisdiction. They also tend to be one of the few public sector agencies with field personnel and heavy equipment that can be mobilized on short notice and expedited contracting capability to rapidly bring in additional assistance. They also have expertise and experience in the application of remote sensing and analysis tools like global positioning systems (GPS), drones, geographic information systems (GIS).

Ultimately, the ability to apply the capabilities of transportation to support emergency conditions depends on the characteristics of any particular disaster and disruption and, more specifically, their spatial and temporal characteristics. For example, the application of regional freeway contraflow to support regional mass evacuations needs a lead time to assemble appropriate personnel; position barricades and implement controls; inform travelers. Thus, it tends to be most appropriate for geographically large slow-moving hazards like hurricanes that threaten vast areas, but can also be forecast several days in advanced. Threats like terrorist attacks, explosions, etc. which give little-to-no-notice typically only permit after-the-fact responses. This is why it is critically necessary for transportation agencies to work hand-in-hand with emergency planners to assess potential hazards, threats, and vulnerabilities and create proactive plans and maintain routine coordination, collaboration, and communication, not only after an emergency occurs.

Examples of expertise, activities, methods, and equipment that transportation agencies have brought to past disasters and could bring to those in the future, span several different areas of activity. In general, transportation associated with emergencies is oriented toward maximizing and maintaining safe, consistent, and rapid mobility throughout an event. Traffic planners and engineers also work with emergency managers to suggest strategies to help move traffic in different types of scenarios, situations, and identify resources required. Transportation professionals also coordinate and manage modes; monitor control systems (like traffic signals); and can use tools and technologies to gather data and model scenarios and response strategies to inform emergency managers on what conditions would likely happen under various management strategies. These generally fall into actions that focus on:

- operational methods to maintain, if not increase, the speed, amount, and efficiency of movement, including:
 - coordinating signals and adaptive traffic control using real-time data
 - implementing emergency control strategies (e.g., intersections turn restrictions)

- bus-only routes
- lane closures
- freeway ramp closures
- contraflow
- manual intersection control
- protected pedestrian traffic
- demand management methods to seek to lower surges in demand, often by spreading it over time and/or space to most effectively utilize available network capacity, including:
 - coordinate in-bound response vehicles.
 - provide transportation to mobility limited individuals
 - transportation demand management actions
 - emergency high-occupancy vehicle requirements
 - phased evacuations
 - shelter-in-place options
 - embargo certain vehicles/modes
 - pedestrian and bicycle strategies
- incident response and emergency communications to monitor and communicate information to travelers and emergency decision-makers, including:
 - monitoring roadways and signals
 - applying closed-circuit TV and variable message signing
 - utilizing highway advisory radio
 - aviation/airspace management and control
 - roadway incident management and motorist assistance patrols
 - fuel and personal service facilities
 - Maintenance/construction lanes cleared
 - Tow trucks deployment
- The application of personnel, equipment, and technologies to maintain, and/or restore infrastructure that support the movement of people, vehicles, and material, including damage and impact assessments.

Biography

Brian Wolshon has over 30 years of experience as a practitioner, researcher, and educator in traffic and transportation engineering, particularly related to emergencies, evacuations, and resilience. He is currently appointed as the Edward A. and Karen Wax Schmitt Distinguished Professor of Civil Engineering at Louisiana State University and has served as the founding Director of the *Gulf Coast Research Center for Evacuation and Transportation Resiliency* for more than a decade. In 2001, Dr. Wolshon founded the Transportation Research Committee on Emergency Evacuation and, for 17 years, served as its Chair. He served in visiting professor and researcher positions at Beihang University, China; the University of Hawaii; the University of New South Wales, Australia; and both the Sandia and Los Alamos National Laboratories. He has authored dozens federal reports, book chapters, and more than 80 scientific journal papers, including numerous seminal works related to evacuation planning and engineering. He has also served as an expert consultant to dozens of federal, state, and local government agencies and engineering firms throughout the United States and as appeared in more the 200 media interviews for outlets like *The Discovery Channel*, CNN, CNBC, MSNBC, Fox News, NPR, *The New York Times*, *USA Today*, and *The Times of London*.

Introduction and Overview

Characteristics of Public Transport-Related Big Data

The role of “big data” and the changes they start bringing to our transport systems are manifold and significant. Besides offline and real-time planning applications for existing transport services, new forms of transport such as ridesourcing and ridesharing would not exist as they rely on processing a large amount of real-time demand data and utilizing these for providing data on vehicle locations and available rides. The business model of ridesourcing services depends on such big data in that pricing is dynamic and based on demand predictions. Big data used in particular for public transport planning, however, go far beyond directly obtained demand and supply data as this chapter will discuss.

To note at the beginning of this discussion is that there is no unique definition of what makes data to be termed “big.” [Milne and Watling \(2019\)](#) provide a comprehensive discussion on big data for transport planning in general and discuss various definitions including their size, dimensionality, relation to other data, and general complexity in analyzing them. Clearly “big” only partially refers to data volume. Big data are usually nonpurpose driven data collected originally for other purposes and then explored for additional value regarding, for example, transport planning. Therefore, the majority of the data will be meaningless and do not contribute to the secondary question explored but one has to filter out the relevant information. This means that machine learning tools are usually employed together with big data in order to facilitate the exploration. One of the early, widely defined definitions is by [Laney \(2001\)](#) who refer to the 3V characteristics of big data, namely “Volume, Velocity, Variety”. (See also article 10601 on big data for various travel modes.)

Public transport planning relevant big data are generated by various sources and at various stages during a journey as shown in [Fig. 1](#). The clear distinction of the different stages and the multiple, often disintegrated, data sources relating to these stages is a distinguishing point between public transport and car traffic related big data. Another distinguishing point is that public transport inevitably generates big data related to ticket purchase. In the case of car traffic, some roads are priced but area-wide pricing of the whole journey appears to be not yet in place (see also article 10759 on data sources for transport modes and 10047 on transit management).

In the following, the data related to these stages and their importance for planning is discussed. The discussion is first held generally before some differences in importance and availability of data for different modes are discussed. Thereafter the different data generation methods/technologies for these stages are discussed including analysis examples. The overview is then complemented with a discussion on the use of big data generated by other, external systems for service planning before conclusions and further reading are pointed out.

Overview of Data Generated by Journey Stage

[Fig. 1](#) illustrates the general types of data that one might obtain with respect to public transport journeys. A journey will start at an origin that is usually different from the first boarding point. Understanding not only the first and last stops of a journey but travel patterns from the “true” origins and destinations, that is, the places where activities take place, is of importance for public transport planning for a range of reasons. First, it will relate to stop choice of customers so that impact of service changes might be mitigated by passengers adjusting their public transport journey by accessing different stops as their first boarding point. Understanding places

Figure 1 Journey stages and data sources

and types of activities is furthermore important to be able to understand and predict demand fluctuations with respect to external factors such as impacts of weather, opening of shops or other land-use changes (see also articles 10021 and 10367 on transit demand estimation and forecasting). The transport planner might further want to obtain information as to the pre-trip information accessed by travelers. Enquires about available connections could give an idea about latent demand as well as about connections not traveled but considered by (potential) customers. If both pre-trip information and actual journeys made can be observed it will provide information as to the flexibility and sensitivity of travelers in terms of departure time as well as actual routes taken with respect to variations in service attributes (see also article 10020 on value of different journey stages).

Understanding the access and egress modes as well as travel times helps establishing measures of service quality. Clearly longer access times from homes and places of activities will generally lead to more demand sensitivity with respect to competing modes. Observing access and egress modes will also help planners understanding requested facilities at stations such as required taxi stands or bicycle parking places. Finally, it will help planners to understand demand fluctuations due to for example congestion on other modes.

The next stage of a public transport journey is the time spent at a stop, station, port or airport, which in this chapter is generally referred to as stop. The time varies greatly by mode but also by other factors. One goal of (big) data being collected and analyzed is to improve services and provide users information so as to minimize the time spent at stops. This can be achieved either by service improvement such as co-ordination of timetables or by providing information which help users to plan their trip. Installing sensors at stops will hence help observing time spent at stops, as well as factors such as crowding, and queues that determine service quality. Observing behavior at stops can, furthermore, give indications as to route choice strategies of passengers.

Similar information can be collected also at transfer stops and the final alighting stop as indicated in the figure. Observing information about (likely) behavior at transfer points is often easier to obtain than for first stops as the time spent at a transfer stop might be also obtained from on-board sensors. If traveler behavior is inferred from on-board sensors, then, a difficulty is, however, distinguishing pure transfer-related activities such as waiting, walking and time required to purchase and validate tickets for the onward journey from other activities that one might do either to bridge the waiting gap or that were planned and according to which the traveler was willing to spend more time at the stop. This is relevant for both short waits at bus stops as well as long waits at stations or airports. One might choose willingly to wait longer if there are a range of attractions at/near the transfer point.

Vehicle and on-board sensors in their various forms can give the planner further a wide range of information. Vehicle tracking provides travel time and service reliability related information, sensors inside the vehicle can observe crowding and boarding/alighting patterns. This has to be distinguished from origin destination information. In most cases on-vehicle sensors are not person specific so that alighting ratios or likelihoods might be established but not alighting points of specific passengers.

Fig. 1 further includes information obtained from payment systems. These can be paper tickets or electronic tickets in their various forms. Whichever the form of payment, the fare structure will determine the detail of information that can be obtained. In flat fare, open systems often only a single tap-in or tap-out is required so that the planner cannot obtain directly origin destination information.

Big Data for Long-Distance Versus Local Public Transport Network Planning

The above discussion has been kept general and “mode-independent” as it relates to all public transport modes. A useful distinction can be made, however, regarding data needed and obtained for long-distance versus short distance, local public transportation planning.

For long-distance travel in general fare structures tend to be distance-based. Furthermore, for service quality and service control purposes, tickets for long-distance journeys are often personalized and for specific seats. For all of these reasons usually both

boarding and alighting stops are observed as well as transfer points from payment systems including gate checks or on-board checks. As a consequence of this, passengers have far less decision points while on long-distance journeys. Their itinerary is fixed, decisions to be made during the journey are mostly how to spend time waiting as well as what to do in case of disruptions or delays. The pre-journey decisions on which connection (and carrier) is chosen are therefore the main focus of big data analytics. (Not least because different journey schedules usually also mean different operators gain profit). Surveys and big data driven analysis of information accessed by travelers before purchasing tickets have become an important marketing research field. Skyscanner has, for example, analyzed search data from its widely spread application to analyse demand patterns and suggests the potential for AI methods on its (big) data (Skyscanner, 2019).

Access and egress for long distance modes is in many cases by other local transport modes so that also more often data are available, for the access to the station/(air)port, but not necessarily the true origin. Other differences are mode depending. For airplane journeys and high speed rail services (a least those on dedicated tracks such as the Japanese Shinkansen) noteworthy is that the on-board travel time undergoes far less variations as the mode does not suffer from interference with other modes. Therefore, collecting information about link travel times is less required. Instead, especially for aviation, the delay sources at the stops, that is, the nodes of the graph, are manifold, stemming from both demand and supply. For local bus journeys, instead, delays on links connecting nodes are frequent. Delays at bus stops might also occur but can be more easily classified as they are largely due to demand factors.

Data Types and Analysis Possibilities by Journey Stage

Pre-Trip Planning

Pre-trip information as to how a person came to choose a specific public transport itinerary are generally difficult to obtain unless activity patterns are known and a person's preferences can be inferred from other, previous choices. For irregular decisions, as well as to understand choices in complex situations with many alternative options, journey planner engines can be mined. The example of "skyscanner enquiries" was noted above. In case the engine is not connected to ticket sales, as usual for local public transport, the main issue is that the matching of enquiries with actual choices is in most cases impossible.

Exceptions are if the journey planner includes a possibility (and, importantly, user consent) to track the person during the day. An example of this is the "Kyoto Arukumachi" application. Upon installation users are asked if they consent to provide their GPS location around the times of enquiry. The multiple GPS records around the time of enquiry as well as the requested information on possible bus routes to a destination possibly allow one a deeper understanding of the person's desired service and actual route chosen (Fig. 2).

Figure 2 Observed GPS points of a (presumably) tourist with data from the "Arukumachi" application of Kyoto City, Japan. For the same user information on bus route information enquired from the application is available.

Pre- and Post-Trip Activities

Traditional national or regional travel diary surveys that aim to capture all trips usually include questions on trip details including access and egress from stops to places of activities as well as on trip purposes. Nowadays, a common way to replace such costly data collection efforts is instead to create a smart phone application that allows GPS tracking a sample of persons (Calabrese et al., 2014).

To obtain activity related questions the application is often supplemented with short pop-up surveys that enquire the purpose of the journey. Other big data based approaches to obtain pre- and post-trip activities of travelers are based on inferring travel activities from non-travel data. For example, integrated payment systems where the same card can be used across stores can be used to infer the travel activities. Payment systems where the same card can be used to pay for public transport systems, such as the Octopus card in Hong Kong, make such an analysis even easier (though again, privacy issues have to be considered.)

GPS tracking, if accurate enough, allows also inferring access and egress modes, route and time. For example, Marra et al. (2019) describe in a recent contribution a tool to observe person's travel to bus stops and route choices based on low frequency GPS data obtained via a smartphone application. Other possibilities to infer this information for larger public transport stations are by observing the doors/gates through which the person enters the facilities. For large transfer points also the time-stamp data from passing arrival gates can provide information as to which previous connection the traveler might have taken.

At Stops

Next to pre-trip information, behavior at stops is least observed, especially for local public transport trips. Unless there are accurate tracking applications or video cameras the arrival time at stops and the queuing behavior for specific bus lines appears to be rarely observed. Data technologies based on Wifi-request signals or Bluetooth signals of travelers offer, however, new applications (Ben-Moshe et al., 2014). The regularly sent request signals of mobile phones allow one to understand the time spent at a stop (if the Mac-address is not randomized) or at least to obtain some information as to how many Wifi/bluetooth enabled devices are at the vicinity of the stop and hence how many persons are likely waiting for a service. Possibly one is also able to observe if travelers leave the stop in case of delays. Difficult to observe will, however, be "detailed strategies" such as when a person is willing to change to a less preferred bus line leaving from the same stop due to delays to his preferred line. For example, observing that passengers destined for a stop that is served by both lines A and B do not board the slow bus A if the fast bus B arrives soon, will give an indication as to trade-off between waiting and travel time.

On-Board

The main two data sources collected by sensors on-board that have been utilized numerous ways for planning applications are automatic vehicle location (AVL) data and automatic passenger count (APC) data. AVL data are collected either by tracking the vehicle through GPS sensors or by signals exchanged between vehicles and stops so that the location of the vehicle can be updated. AVL data are the foundation for passenger real-time information as well as for control strategies to maintain desired headways between services and to avoid "bunching". AVL data might further be utilized to analyze dwell time information at stops which provide some information about demand patterns. APC data provide information about boarding passengers and alighting passengers, but not OD matrices. Through variances in boarding and alighting demand the latter might be inferred, however. Furthermore, the understanding of on-board passengers from APC data are an important data source for service capacity planning. The possibilities offered by this data source are discussed in more detail in Furth et al. (2006). As a specific application example, Pi et al. (2018) used both AVL and APC data to measure the performance of a public transport system in the Pittsburgh region. (See also article 10445 on transit operations for further reading.)

Boarding and Alighting Points

The data collected via the different payment systems for public transport are one of the most important data sources for public transport planning. For long-distance public transport clearly ticket sales are the most direct information on overall demand (except latent demand due to capacity issues) and demand patterns.

For local transport where tickets are not run specific, electronic ticketing through "smart cards" has brought significant analysis possibilities. To note is that the data fit the notion of "big data generated for different primary purposes." The primary purposes of smart cards are reduced cash handling, convenience for passengers, integrated fare collection and enabling a fair revenue split among several operators. They furthermore allow operators easier implementation of advanced fare structures. For example, "price capping" where users are not charged above a certain limit if they make several journeys would not be feasible without recording of the paid fares. Also loyalty point systems where users obtain discounts or rewards (in some form) for regularly usage of a service are not possible without smart cards.

Exploration of smart card data for additional "secondary" purposes, however, is the main academic interest as discussed in the book "Public Transport Planning with Smart Card Data" (Kurauchi and Schmöcker, 2016). Construction of origin-stop to destination-stop profiles has been a major research area, since in many cases, especially bus systems, passengers do either only tap-in or tap-out. In case of distance-depending fares, as for most metro services, where passengers tap-in and tap-out, a challenge remains to

identify the transfer points and routes taken. Destinations and transfer points are often inferred by considering onward connections as well as long-term patterns of passengers. Routes can be estimated from transfer points (if observed) as well as travel times and considering schedule information or AVL records of runs. A number of contributions have looked into inferring activities of passengers by considering the land-use around origin and destination stops, duration time before records of subsequent journeys as well as regularity patterns of the users. Sensitivity of user behavior with respect to service disruptions is another analysis area. Smart card data can be used to observe immediate changes in network flows, as well as, if the disruption is longer, user adjustment before, during and after the disruption. Similarly, with longer term smart card data, adjustments of users to, for example, schedule, service frequency changes or other policy interventions can be observed, though the literature on long-term data analysis of smart card data appears to be still thin. [Pelletier et al. \(2011\)](#) review the analysis of smart card data (up to that year) and discuss that the data can be used for “strategic (long-term planning), tactical (service adjustments and network development), and operational (ridership statistics and performance indicators)” purposes.

Besides user behavior-related analysis, through fusion of smart card data with other data, among others, service quality indicators can be obtained or spatial and temporal equality and fairness of a public transport service can be assessed. The smart card data can also be used as surrogate for information obtained from on-board sensors, if these are not available. For example, the time of first and last tap-in or tap-out at stops can be used to estimate the arrival and departure time at stops. For buses, where tap-in and tap-outs are occurring on-board, further they can replace on-board counts. In metro systems where the tapping is mostly occurring at gates, for passenger load estimates on specific runs, one needs to estimate the time from and to the gate as an additional source of uncertainty in the estimation process.

To remark is that smart cards tend to become replaced by alternative payment systems. Credit cards with which one can tap-in directly, mobile phone apps that allow payment through close range communication or based on GPS tracking are fast increasing. The data content and hence how these data are explored will be the same or enhanced if the payment data can be combined with other data from the credit cards or mobile phones and if user consent is obtained.

Big Data Generated by Non-PT Sources

Finally, it needs to be stressed that there is a whole range of other non-public transport big data that can be directly utilized for public transport service planning but do not provide journey stage specific information. Big data from other transport modes and data unrelated to transport might here be distinguished. For the former, taxi probe data or electronic toll collection for cars are a good example. These will give a good indication of travel times on links used also by public transport services. An example for the latter group are again data possibilities through mobile phone data. In contrast to the formerly described records obtained through bespoke applications, also non-application based storage of aggregate or disaggregate movement and population density data provide the operator with useful information.

Aggregate data on “mesh basis” can be utilized to obtain information regarding how many persons are in a specific time in a specific mesh. In some cases also mesh movements can be obtained. Both sources can inform public transport operators regarding potential demand and provide some information as to how much demand is moving by public transport if the data are compared to historic ridership data. Disaggregate GPS tracks of individuals are (and should be) restricted in most cases, but obviously, could provide a large range of the above discussed data on access and egress tracking, activity information as well as even regarding lines used. The data can further provide one with information on travel times between parts of the city and can be the basis to evaluate where public transport is competitive or not. The book “Mobile Technologies for Activity-Travel Data Collection and Analysis” by [Rasouli and Timmermanns \(2014\)](#) provides an overview and range of applications on this subject.

Beyond such data, one can imagine a range of “innovative usage” of other big data; following are a few examples: Scanning of social media data can provide information about public transport perceptions and routes (not) recommended. Sales data and shopping customer flows obtained via various sensors can be used to understand and predict patterns in public transport usage behavior. Similarly, mining data on hotel bookings or sightseeing and correlating these to factors such as weather, seasonality, events or even reliability of the public transport service itself, can be a potential source for data prediction. It clearly has to be emphasized once more that for all these applications, in particular the “innovative” ones, ensuring data privacy issues need to be a primary concern.

Conclusions and Further Reading

The purpose of this contribution has been emphasizing the different big data sources and their analysis potential for public transport planners. Less emphasis has been given to the resulting practical implications for operators, travelers as well as modelers/planners. For this we refer to the longer review by [Welch and Widita \(2019\)](#) structured according to applications and methods.

An important overall message of this chapter might be summarized as follows: Big data has led to smart travelers and smart operators. This point is also discussed in [Milne and Watling \(2019\)](#) but not specific to public transport. Travelers are better informed to make time and cost minimizing choices and operators can develop better transport networks and better real time control strategies ([Fonzzone et al., 2016](#); [Wilson and Hemily, 2016](#)). This is leading, however, to numerous research challenges not only in terms of

how the data can be utilized but also in modeling the more complex decision makers of travelers and the interaction with control strategies as is discussed in the book edited by [Gentile and Nökel \(2016\)](#) which is recommended as further read on transit modeling.

Finally, it needs to be noted, that to keep this contribution within the given length limitation, only relatively few references have been given. It is beyond this chapter to give adequate references to all work as the literature is vast. The given references often link to books as well as review and other overview papers to which the reader may be referred to.

Introduction

The overarching term “active transport” includes all transport modes which require physical activity to reach a destination. Active transport is a quite recent term; traditionally, walking and cycling were categorized as nonmotorized modes of transport (Gerike and Parkin, 2016). This definition can have negative connotations in that nonmotorized transport modes comprise everything else but motorized vehicles. This more narrow perspective suggests low level of attention and priority given in this direction as compared to motorized transport modes. The term “active transport” has a completely different connotation. It suggests positive dynamics and attracts higher attention; active modes are not on the periphery but are to be treated with equal regard along side the individual and public motorized transport modes both in political discussions and in level of assigned priority. The increased acceptance and usage of the term active transport thus reflects the substantial growth of and support for walking and cycling that can be observed in many cities and countries worldwide.

The term active transport also allows for electric support of the human-powered vehicles as this is the case for electrically assisted bicycles such as pedelecs: These belong to the active transport modes as long as human power is necessary for moving forward. The term “vulnerable road users” is also used for summarizing walking and cycling in the context of safety analysis and management. Further terms such as “slow modes” also are in use but are less present in the academic and non-academic terminology.

The variety of bicycles has increased substantially in recent years with growing numbers of special bicycles such as cargo bikes, bicycles with trailers, folding bikes, tandems, for example, for parents with their kids, or electrically assisted bicycles. In addition, the new solely electrically powered micro-vehicles such as the electric scooters are currently spreading worldwide. These share many similarities in their characteristics and requirements with cyclists. This chapter focuses on walking and human-powered cycling, particularly when it comes to drivers and barriers. Empirical evidence on users and usage of the new electrically powered micro-vehicles is, thus far, fragmented; it documents the high dynamics triggered by these innovative services and vehicles but does not give a consistent picture of users and usage. All traditional and innovative forms of micro-mobility are considered in the discussion of measures for promoting active transport and micro-mobility in the second part of this chapter.

This chapter is structured along three main parts. Following to the introduction, main characteristics of walking and cycling are described. The subsequent section *Drivers and Barriers* summarizes determinants of walking and cycling as identified in the literature: What makes people walking and cycling and what are important barriers? Based on this knowledge on characteristics and determinants of active transport, recommendations for policies and strategies for promoting walking and cycling are developed in the last part of this chapter.

Characteristics of Active Transport

Common Characteristics of Walking and Cycling

Pedestrians and cyclists are vulnerable street users; they do not have any physical shell that protects them in case of an accident or fall. Both modes are far more space efficient than the motorized modes due to their smaller dimensions and slower speeds. Standard pedestrians have a width of mostly 0.80 m and bicyclists of 1.00 m according to international guidelines on urban street design; the design car has a width of around 1.80 m and needs additional space on both sides for rear-view mirrors and lateral movements (Gerike et al., 2019). Lanes for pedestrians and bicyclists are thus narrower compared to lanes for the motorized modes and, in addition, have higher capacities measured as moved users per hour.

Both active modes have low or no emissions in terms of noise, air pollutants and greenhouse gases. They are flexible in space and time. Users can walk or cycle wherever and whenever they want to; they do not depend on any fixed schedule of public transport services or dedicated parking facilities for cars. Walking and cycling require little to no money, presenting low costs for users, operators, and society as a whole. Walking and cycling also contribute to public health objectives as they are one type of moderate physical activity and thus improve quality of life and health (Mueller et al., 2015).

With these common characteristics, active transport is located at the intersection of urban planning, transport planning, and public health. Active transport supports the achievement of objectives in all three of these disciplines. At the same time, stakeholders from all three disciplines can foster active transport through their specific policy measures and expertise. Joint efforts efficiently allow for the maximization of synergies and the attainment of the common objective of increased walking and cycling levels.

Walking

Walking is the slowest of all transport modes. Pedestrians are therefore very distance and detour sensitive. They need direct connections between their origins and destinations and hardly respect any detours, for example, when crossing a street after having left the bus. People only walk for short distance trips; 61% of walking trips in Germany are shorter than 1 km (80% for 2 km) (infafas et al., 2018). Dense spatial structures and mixed land-use are therefore paramount for achieving high walking levels. Another consequence of pedestrians' distance-sensitivity is that pedestrian facilities generally need to be designed for movements in two directions; pedestrians will not accept changing the side of the street for walking on one-directional sidewalks. Walking as a transport mode will never be suitable for satisfying all daily travel needs of any one person; it needs to be combined with cycling or motorized modes and shows particular synergies with high quality public transport provision (Gascon et al., 2019).

Unencumbered walking does not require any specific equipment or skills; it is a human desire from the very early to the latest of life stages. For many, walking represents a form of independence, self-confidence, social participation, and health. These specific characteristics of walking lead to the phenomenon that the pedestrians group is the most heterogeneous one from all transport modes and includes the whole of society with all social and age groups, people with and without mobility restrictions, women and men, etc. Another consequence of this inherent human desire to walk and to move is that people do not reflect on walking. It is a strongly habitual activity and as normal as brushing one's teeth. As a result, people do not remember walking trips and activities as reliably as trips with other transport modes (Aschauer et al., 2018). Pedestrians are flexible in terms of the quality of walking facilities and the physical environment—high pedestrian volumes are found even for narrow sidewalks and at streets with high traffic loads (Kim et al., 2019). At the same time, the literature shows that walking behavior is influenced by the streetscape, the quality of the public space, and the characteristics and usages of the buildings abutting the street and in the neighborhood (Ewing et al., 2016; Gehl, 2010; Mehta and Bosson, 2018; Mehta, 2013).

Due to their low speed, pedestrians can spontaneously stop or change direction which leads to conflicts with bicyclists if both use the same space in the street. Walking not only serves movement but also place functions. When people walk to reach their destinations, streets serve as conduits that should enable all user groups to move safely and comfortably. Pedestrians also use streets as destinations for carrying out 'place activities'. These include: (1) necessary activities such as waiting for the bus; (2) optional activities such as eating or watching the street; and (3) social activities in the form of communication which require the presence of further persons (Gehl, 2010). The objective functions for movement and place functions are completely different: the maximization of moving comfortably and safely vs. the maximization of the number and duration of place activities, respectively.

Pedestrians, that is, those walking as a transport mode, hardly have any lobby support in political discussions. Important reasons for this are that no technology is needed for walking and that no walking industry exists; in addition, all societal groups are (potential) pedestrians. With the exception of safety, almost no data exist on walking, nor do any measurable political goals or monitoring systems, thus significantly reducing the ability to report on the statistics or the successes of walking as a transport mode.

Cycling

Cycling, in contrast to walking, is a conscious activity. Bicyclists and non-bicyclists have a clear opinion about cycling and about why they personally cycle or do not cycle. The level of cycling depends far more than walking on high quality infrastructure. Seamless, comfortable, and safe cycling facilities substantially contribute to higher cycling levels (Mueller et al., 2018). Many municipalities have invested and are still investing high efforts into improving cycling facilities leading to substantial increases in cycling levels in many places in recent years (see <http://www.epomm.eu/tems/for> an overview of modal split developments in various European

cities). The type of cycling facility as well as the rules for deciding which cycling facility is suitable for each setting differ greatly between countries and also between municipalities within one country (Gerike et al., 2019). One reason for this is that cyclists are the only street user group that can be provided either in the carriageway together with or next to the motorized transport modes or on the footway together with pedestrians.

Cycling requires a bicycle, suitable clothes, and safety gear (e.g., a helmet, reflectors, etc.). Cyclists are more affected by varying weather conditions than pedestrians as they are less protected (e.g., they cannot take an umbrella) and more sensitive to slippery or snowy surfaces. In contrast to walking, this leads to substantial differences in cycling levels depending on the season and climate. One of the main barriers for cycling is the inherent higher demand for physical effort (than, e.g., walking), particularly in hilly areas (Handy et al., 2014; Heinen, 2011).

Cycling speed is also increased and is in urban areas almost equal to the motorized modes (when looking at the complete trip, including all stages from the origin to the destination). Such relatively high speeds allow for longer distances than for walking. 31% of all cycling trips range between 2 and 5 km—this appears to be a feasible distance for many cyclists. 11% of all cycling trips are 5–10 km long, and 6% of all cycling trips are even longer (infas et al., 2018). The higher availability of electrically assisted bicycles might further increase the proportion of longer cycling trips. For all transport modes, 58% of trips are shorter than 5 km and 74% are shorter than 10 km; thus, in terms of distance, cycling is well suited for covering daily travel needs. It can also be used for transportation of relatively large and heavy items, enabling cycling as a transport mode for most distances and trip purposes. Synergies with public transport nevertheless also exist for cycling.

The proportion of mandatory trips (work, education and, business) is higher for cycling than for walking. Therefore, once a person decides to cycle, this behavior remains more stable than walking for leisure as the main trip purpose (infas et al., 2018). Another result of the higher speed of cycling is that personal security is less of an issue than for walking, but safety in general and, more particularly, perceived safety of cycling facilities are more important.

Drivers and Barriers

Overview

Various conceptual frameworks concerning drivers as well as barriers for active transport are available in the literature (Götschi et al., 2017; Koszowski et al., 2019). There is consensus that multi-level and multi-disciplinary approaches are required in order to understand and to purposefully shape walking and cycling. One important determinant of active transport is the built environment which includes urban structures, land-use, and transport supply. It has an impact on travel behavior in general, but specifically on active transport on the regional, city, neighborhood and street levels. The whole transport system must be considered in order for active transport to be well understood. The most efficient measures for promoting active transport could potentially be those which address motorized modes, for example, through the improvement of public transport supply or the restriction of car traffic.

Socio-demographic, socio-economic, and socio-psychological variables are relevant at the levels of single persons, households, peers, and the (neighborhood) community. The distinction between objective and perceived quality of the available built environment and transport services is imperative; for example, objectively safe cycling facilities will not be used if they are perceived as risky by the (potential) users. Implemented policy measures and feedback loops for promoting active transport can change the system and bring dynamics into the conceptual frameworks of active transport. Policies can directly influence travel behavior when, for example, new walking and cycling infrastructures are implemented. Policies might also indirectly influence travel behavior through a change in overall attitude and mindset. Policies should also address governance structures including institutions, processes, finance and legal issues.

Person and Household Characteristics

Socio-demographic and socio-economic characteristics are important indicators for the propensity to walk and to cycle (Gascon et al., 2019; Handy et al., 2014). Walking levels are highest in the youngest and oldest age groups with hardly any differences between women and men (infas et al., 2018; Harms et al., 2014). Cycling levels are more evenly distributed across age groups and gender in countries with high modal-split proportions of cycling whereas, in countries with lower cycling levels, mainly young men cycle (Götschi et al., 2015). The age group of 9–17-year-old children and adolescents shows a high affinity toward the active modes (Harms et al., 2014). Through modelling their own travel behavior and setting an example, parents have a primary role in shaping their childrens' travel behavior and for shaping independent travel in early years (Ghekiere et al., 2016). The odds of walking and cycling increase with higher levels of education (Handy et al., 2014); however, findings on the influence of income on active transport are inconclusive (Koszowski et al., 2019).

There is consensus in the literature regarding the influence of the ownership of a driving license and the availability of motorized vehicles. Both factors inhibit active transport and encourage people to adopt car-oriented travel behaviors (Clark and Scott, 2013; Damant-Sirois and El-Geneidy, 2015). Accordingly, better availability of bicycles in a household increases the propensity to cycle (Heinen et al., 2011).

Socio-psychological factors such as perceptions, preferences, attitudes, habits, perceived controls on behavior (e.g., linked with the ability to carry luggage or to ride a bicycle), and social and personal norms are generally found to determine individual mode

choice, more specifically active mode shares. The theory of planned behavior is often applied in this context (Ajzen, 1991). Affirmative opinions about active transport are positively correlated with active transport levels in a bidirectional causal relationship (Kroesen et al., 2017). Motivating factors for cycling include status and lifestyle promotion, mental and physical relaxation, comfort, time savings, privacy and security (Heinen et al., 2011). Heinen (2011) lists the following individually perceived barriers for cycling: time loss compared to motorized transport modes, overly long distances to relevant destinations, bad weather, lack of parking facilities for bicycles, physical overload (e.g., caused by differences in altitude or insufficient fitness and sweating). The influence of subjective motivational factors on walking is less clear than for cycling. For walking, the built environment is of highest importance as described below.

Density of Spatial Structures and Diversity of Land-Use

The “5 Ds” (Density, Diversity, Design, Distance to public transport, and Destination accessibility) are consistently significant and influential particularly for walking (Ewing and Cervero, 2010; Gascon et al., 2019; Lai and Kontokosta, 2018). Ewing et al. (2016) demonstrate the specific relevance of Density, measured in their example as floor area ratio and population density within a quarter mile of the investigated commercial streets. Diversity is often measured by entropy measures describing the number and variety of different land-use types in a given area (Ewing and Cervero, 2010; Lai and Kontokosta, 2018). Lower Distances particularly to rail-based public transport consistently and significantly increase pedestrian volumes (Ewing et al., 2016). Design-variables describe the characteristics and, more specifically, the connectivity of the street network, measured, for example, as intersection density or as a proportion of 4-way intersections (Ewing and Cervero, 2010). Destination accessibility describes the level at which relevant activities can be reached (Ewing and Cervero, 2010). Destinations are operationalized, for example, by the number of nearby stores and amenities weighted by their distance; these are hardly significant and show an overlap with Diversity.

Urban design and land-use are less important for cycling than for walking (Buehler et al., 2017). Thanks to higher speeds, longer distances can be covered with the bicycle resulting in less dependence on the proximity of relevant destinations. The range of bicycle trips further increases with higher availabilities of electrically assisted bicycles in the population and the extension of bicycle facility networks that allow for high speed and cover larger areas, for example, on the regional as well as municipal levels.

Connectivity and Density of Walking and Cycling Networks

Mixed findings exist for the design variables related to the connectivity and density of infrastructure networks as introduced above. These are significant in some studies, in others they are not (Ewing et al., 2016). Hooper et al. (2015) find positive correlations, the higher the street connectivity and the higher the accessibility to commercial land-use within the neighborhood, the higher the odds of walking. Cervero et al. (2009) find that residents in neighborhoods with highly connected street networks tend to have higher active transport levels of a minimum of 30 min/day on average. A high connectivity is mainly related to fine-grained street networks with many intersections [nodes] and requires many route options to get from each starting point to the respective destination. The shorter the distances are between the intersections, the higher the share of pedestrians and cyclists in the local modal split (Ewing and Cervero, 2010; Kaplan et al., 2016). Various studies confirm the importance of the density and connectivity of the network of cycling facilities for achieving high cycling levels (Damant-Sirois and El-Geneidy, 2015; Handy et al., 2014; Mueller et al., 2018).

Comfort and Safety of Walking and Cycling Facilities

A safe and comfortable infrastructure is as important for cycling as urban design and land-use are for walking. This is in direct contrast to pedestrians who also walk on deficient pedestrian facilities if dense and mixed spatial structures and public transport services generate high walking levels.

The perceived safety of provided infrastructure is hence essential for the acceptance of cycling as a transport mode (Handy et al., 2014). Types of cycling facilities and criteria for deciding on their suitability differ greatly between countries and also between municipalities within one country (Schröter et al., submitted). Countries with high levels of cycling such as the Netherlands or Denmark tend to provide facilities for cyclists located off the carriageway and only allow for mixing cyclists with motorized vehicles in the carriageway with low speed limits of maximum 30 km/h. Cycling facilities should be designed in a way that allows for the accommodation of standard and nonstandard bicycles as well as for all the innovative electric microvehicles that have emerged in the last years and months or that might emerge in the future. The so-called safety-in-numbers effect describes the phenomenon of improved safety for cyclists when the number of cyclists in specific regions or at single infrastructure points such as junctions increases (Elvik and Bjørnskau, 2017). The explanation of the safety-in-numbers effect is bi-directional: Better infrastructures for cyclists potentially increase cycling levels which, in turn, lead to higher visibility and safety levels for bicyclists.

For walking, Kang (2015) and Kim et al. (2019) find significant positive impacts of sidewalk widths, crosswalks, trees, and negative impacts of slope on pedestrian volumes. The number of traffic lanes has a significantly positive influence on walking levels but is highly correlated with the distance to public transport. Lai and Kontokosta (2018) compute a composite variable streetscape as the product of sidewalk coverage, pavement quality, and street amenity. This variable significantly increases pedestrian volumes on weekend days but not on work days.

Quality of Streetscape as Public Space

The “5 Ds” as introduced above are of high relevance particularly for walking not only on the neighborhood level but also for the streetscape itself. This holds particularly for Design but also for the other Ds. [Ewing et al. \(2016\)](#) show the significant influence of floor–area ratios of the streets themselves (computed as the total building floor area for parcels abutting the street, divided by the total area of tax lots) and of the proportion of retail frontage along the block face on pedestrian volumes.

For the D-variables on the street level, the streetscape itself also matters for walking. Transparency is defined as the degree to which people can see or perceive what lies beyond the edge of a street. This is measured, for example, by the proportion of first floors with windows and of active uses of adjacent buildings, and significantly increases walking volumes ([Ameli et al., 2015](#); [Ewing et al., 2016](#); [Hamidi and Moazzeni, 2019](#)). [Ewing and Handy \(2009\)](#) define, based on expert ranking, further relevant variables for walking; these are imageability, enclosure, human scale, and complexity. These are significant in some of the few existing studies that empirically analyze their influence on walking volumes ([Ewing et al., 2016](#); [Gehl, 2010](#); [Mehta and Bosson, 2018](#)).

[Ewing et al. \(2016\)](#) view transparency as the most important urban design quality on the street level; they analyze the influence of the following three variables separately: proportion of windows, of street furniture, and of active uses. The latter two are found to significantly increase pedestrian volumes. Overall, the three streetscape design features add significantly to the explanatory power of the statistical models explaining pedestrian volumes compared to models with only the D-variables on the neighborhood and street levels. Street furniture includes signs, benches, parking ticket machines, trash cans, newspaper boxes, bollards, street lights as well as anything at the human scale that increases the complexity of the street. Public seating is found to be of particular importance. The active use includes shops, restaurants, public parks, and other uses that generate significant pedestrian traffic. Inactive uses include blank walls, driveways, parking lots, vacant lots, abandoned buildings, and offices with no apparent activity.

Policies and Strategies for Promoting Active Transport

The aforementioned similarities and differences between walking and cycling directly translate into policies and strategies for their promotion. Both active modes benefit from integrated strategies that aim on the one hand at strengthening walking, cycling and also public transport and on the other hand at restricting car use. Improvements of public transport services are important in this context, particularly when walking levels should be increased. Measures for restricting car use are of highest relevance for promoting active transport; fast access to destinations by car and comfortable parking facilities at the destination are one main barrier for choosing to walk (often in combination with public transport) or to cycle. Examples for these restrictive measures are the re-allocation of street space to active modes or public transport (as in, e.g., London) ([Wittwer et al., 2019](#)) or parking management—when the number of car parking facilities is reduced, their prices are increased or the maximum parking duration is limited.

Both walking and cycling benefit from public health campaigns and activities aimed at stimulating active transport as physical activity. One of the core objectives in the Mayor of London’s Transport Strategy is that by 2041, all Londoners should do “at least the 20 min of active travel they need to stay healthy each day” ([Mayor of London, 2018:22](#)).

The main barrier for walking specifically is distance. Dense and mixed land uses are therefore key for the promotion of walking. On the detailed microlevel of a street segment, the ground-floor usages and the design of the façades of the buildings abutting the street are of high relevance and more important than the street design. Pedestrians move slowly and experience their environment intensively, particularly when they are place users in the street. Active frontages and soft edges of the adjacent building invite pedestrian activities and city life whereas inactive walls without any interesting things to see or do cause people to walk more quickly and as efficient as possible to their destination.

Streetscape also matters for pedestrians. Unobstructed through zones with sufficient widths should be provided at the footway for accommodating the expected pedestrian volumes ([Gerike et al., 2019](#)). Seating significantly increases place activities in all identified studies; shade and shelter as well as all measures increasing the perceived attractiveness of the public street space also invite street life ([Mehta, 2013](#); [Mehta and Bosson, 2018](#)). Safe crossing facilities need to be provided at main crossing points at specific locations or in linear forms. The principles of inclusive design need to be respected, particularly when providing for walking in order to enable all user groups to use the available facilities.

Cycling is less dependent on dense urban structures. Seamless, safe, and comfortable infrastructures that accommodate all forms of cycling vehicles are key for achieving high cycling levels. (Potential) cyclists do not cycle when they do not feel safe even when the provided facilities are judged to be safe by planners and further experts. Suitable cycle parking facilities are one integral component of these infrastructures.

Mobility cultures supporting active transport are more important for cycling than for walking. Particularly in starter cities and countries, the uptake of cycling can be accelerated with campaigns, festivals, and further so-called soft measures ([Koszowski et al., 2019](#)).

Conflicts in space and time between pedestrians and cyclists exist. Both compete for the available street space that is clearly limited, particularly in inner urban areas; both compete for green time at signalized junctions. Such conflicts can only be solved on a case-by-case basis based on clear political priorities given on the city level.

Summary and Conclusions

Active transport currently shows positive dynamics in many urban areas and countries around the world. Walking and cycling levels are increasing which goes hand in hand with growing support and commitment from planners and political decision makers. More and more stakeholders agree that there is no alternative to high levels of walking and cycling in combination with public transport and the emerging new micro-vehicle types when shaping future transport systems.

Societies worldwide are facing major challenges with growing cities, congested transport systems, ambitious goals for greenhouse gas emissions, noise, and air pollutants. Highest attention needs to be paid to safety so that achievements in promoting active transport are not compromised by increased numbers in accidents and injuries. More and more stakeholders commit to the Vision-Zero goal: No person should be killed or severely injured in traffic. This is a challenging goal but one key success factor for strengthening walking and cycling.

The promotion of active transport and the design and management of liveable streets is an interdisciplinary task which supports ambitions in urban planning, transport planning, and public health and can be achieved more successfully and efficiently if all the relevant stakeholders collaborate.

Acknowledgment

Funding for the research project “Active Mobility: Improved quality of life in urban agglomerations” has been received from the German Environment Agency—UBA, and the research benefited from the European Union project “PASTA—Physical Activity Through Sustainable Transport Approaches”. This work was also supported by the European project Multimodal Optimisation of Roadspace in Europe (MORE) (<https://www.roadspace.eu/>) which receives funding from the European Union’s Horizon 2020 research and innovation program under grant agreement No. 769276.

Electric Vehicle Concepts

Electric vehicles (EV) are vehicles with at least one electric motor and an electric energy supply system for the purpose of vehicle propulsion. The electric energy supply system can be an on-vehicle electric storage system (e.g., a battery) or an off-vehicle electric power system (e.g., a power grid). Another subset of EVs is vehicles with an additional on-vehicle electric generation system (e.g., fuel cell or solar cell). A further subset of EVs is hybrid electric vehicles (HEV), which contain an additional energy converter (e.g., a combustion engine) and energy supply system (e.g., fuel) for vehicle propulsion.

EVs can be land vehicles (road, rail, offroad, and indoor), water vehicles, air vehicles, and space vehicles. **Figure 1** gives an overview over exemplary electric driven vehicle concepts.

EVs can have various use applications (i.e., such as vehicles with combustion engines). EVs can be used for private purposes (e.g., leisure mobility, commuting) or commercial purposes (e.g., logistics, goods delivery, rental services).

Passenger cars are the most important road vehicle concept in terms of global sales, added value, and global vehicle mileage (and consequently in terms of environmental externalities). Hence, the passenger car market is a major (future) market for EVs. The majority of the passenger car fleet is used for private purposes and owned by private persons. For example, in Germany about 70% of the registered motor vehicle fleet are private cars (DIW Berlin & DLR, 2019). Further applications of passenger cars are rental car fleets, commercial transport (e.g., delivery transport, service transport), company cars, new mobility concepts (e.g., car sharing and ride-sourcing fleets). Given the large field of EV concepts and applications the present article focuses on prevalent EV concepts: EVs for road use having one or more electric motors and a battery, which is charged from the power grid.

Road Electric Vehicle and Charging Technology

Definitions

The subsequent **Table 1** gives an overview of various terms used in the context of EVs. Similar definitions are given, for example, in SAE J1715.

Architectures

An EV can have various architectures. Four typical architectures for two-track vehicles are shown in **Figure 2**.

Architecture I results from the conversion of a conventional vehicle (CV) to an EV either by the manufacturer or a workshop as retrofit. The combustion engine and the fuel tank are replaced by an electric motor and a battery. The clutch and the shift gearbox, which are essentially not required in an EV, remain. Architecture II where the clutch is removed and the shift gearbox is replaced by a fixed gearbox is used in most production vehicles. Architecture III where most transmission components are removed and additional functionalities are enabled such as a distribution of torque to individual wheels for improving vehicle dynamics is used in few production vehicles. Architecture IV where all transmission components are removed and further functionalities are provided, such as a perpendicular alignment of the wheels for parallel parking exists in prototype vehicles. Transmission components induce inertial and friction losses,

Road	Rail	Water
e.g., car van bicycle scooter light vehicle motorbike bus lorry semitruck	e.g., train tram subway cable car	e.g., ferry, trolley boat submarine
	Air	Other
	e.g., helicopter quadrocopter airplane zeppelin	e.g., construction vehicle off-road vehicle space rover

Figure 1 Exemplarily list of vehicle concepts with electric drives.

Table 1 Terms, definitions, and abbreviations used for road electric vehicles

	<i>Label</i>	<i>Description</i>
CV	Conventional vehicle	Vehicle having a combustion engine for vehicle propulsion
EV	Electric vehicle	Vehicle having at least one electric motor and an electric energy supply system for vehicle propulsion (hypernym)
BEV	Battery electric vehicle	EV having a battery as on-vehicle electric storage system
FCEV	Fuel cell electric vehicle	EV having a fuel cell as on-vehicle electric generation system
HEV	Hybrid electric vehicle	EV having another energy converter (e.g., combustion engine) and energy supply system (e.g., fuel) for vehicle propulsion (hypernym)
Micro HEV	Micro hybrid electric vehicle	HEV having an electric storage system which has a small capacity and voltage no permitting electric driving
Mild HEV	Mild hybrid electric vehicle	HEV having an electric storage system which has a medium capacity and voltage permitting electric driving over short distances at low speed
Full HEV	Mild hybrid electric vehicle	HEV having an electric storage system which has a large capacity and voltage permitting electric driving over short distances at medium speed
PHEV	Plug-in hybrid electric vehicle	HEV having an electric energy storage system which has a large capacity and voltage and can be charged from the grid permitting electric driving over medium distances at high speed
REX/ EREV	Range-extender hybrid electric vehicle/ extended range electric vehicle	HEV having an electric energy storage system which has a large capacity for electric driving over large distances

increase production and maintenance costs, raise the weight, require installation space, prevent functionalities and are therefore not desirable. From this perspective the Architectures III and IV are favorable due to fostering new vehicle layouts and functionalities and may thus be increasingly used in the future, particularly in new EV constructions, which are not derived from CV constructions.

Specifications

EVs can be found in essentially all road vehicle classes with a wide spectrum of driving ranges, battery capacities, energy demands, motor powers and maximum speeds. An overview of the typical specifications of EVs in various road vehicle classes is given in **Table 2**. Note that the range corresponds to the distance, which can be covered with a fully charged battery.

For small and medium vehicles (scooter, bicycles, and motorcycles) the specifications of the electric version and the conventional version are very similar. Partly, the specifications of the electric version are even superior, for example, the range of an electric bicycle in comparison to a conventional bicycle. For medium and large vehicles (vans, trucks, and buses) the specifications of the electric version and the conventional version are very diverse. Particularly, the ranges are significantly smaller for the electric variant, permitting only urban and regional usage.

Charging

Battery EVs (BEVs) can be charged in two ways. The battery is operating with direct current (DC) while the power grid is providing alternating current (AC). Therefore, a charger that converts from DC to AC is required. The charger can be installed in the vehicle or in

the charging station. For low-charging power (up to 22 kW, normal charging) the charger is installed in the vehicle and charging is performed with AC. For high-charging power (above 22 kW, fast charging) the charger is installed in the charging station due to its high weight and cost and charging is performed with DC. Electric cars can support AC charging, DC charging or both. For AC charging a standard connector (e.g., Schuko, NEMA) can generally be used. For safety and security, however, specific connectors which permit a communication between the charging station and the EV to control power flow and prevent unauthorized disconnection are utilized for both AC and DC charging. Other connectors are used in separate regions. Relevant standards are IEC 62196 and SAE J1772. The most common connectors and their specifications are summarized in [Table 3](#). Note that these specifications apply for typical implementations. Note further that for small vehicles (scooters, bicycles, and motorcycles) usually Schuko or NEMA connectors are preferred while for large vehicles (trucks and buses) partly proprietary connectors are used. For all other vehicles Type 1, Type 2, CCS, and CHAdeMO connectors have become standard.

For access and payment various concepts exist, for example, RFID or SMS for access and energy- or time-based tariffs for payment. Various initiatives work towards unified and accessible access and payment solutions.

Uncontrolled charging can lead to a significant load in the power grid, particularly in residential areas and at peak times. Controlled charging can substantially reduce the load in the power grid. The basic idea consists in adjusting the charging power and in turn the charging time such that grid limits are respected and at the same time the mobility demands are fulfilled. For controlled charging standards like ISO 15118 and OCCP 1.6/2.0 have been established. Additionally controlled charging can be used for buffering renewable energy (e.g., solar energy). The EV is charged when renewable energy is available (grid to vehicle or G2V) and discharged when renewable energy is lacking (vehicle to grid or V2G).

Assessment of the Electric Vehicle Concept Compared to the Conventional Vehicle Concept

Early versions of the electric motor were already used in the late 1820s to power tiny cars and carriages with nonrechargeable primary cells, while the first practical implementations came to life in the late 19th century ([Guarnieri, 2012](#)). In the early 1900s, EVs became

Table 3 Overview of charging connectors

the primary choice of local motorized transportation. In the 1930s vehicles with gasoline and diesel engine became more and more popular; they managed to overtake the EV leadership through mass production at a reasonable cost and improved performance. Further reasons for a halt in development of EVs were that the need for intercity travel grew and that charging infrastructure and reliable electricity transmission were lacking. It was not until the late 1990s that multiple BEV prototypes were developed and another decade until HEVs were engineered (Situ, 2009). Since then the development has engendered multiple variations of EVs which are being mass-produced and sold today. Their success is not as forthcoming as it was for the EVs in the early 1900s. The share of BEV and HEV in the car fleet in 2020 is still in the single-digit percentage range in most countries. Hence, a market uptake of EVs is required and promoted by various bodies since EVs are seen as one component towards sustainable transportation and they have advantages over CVs. The reasons are manifold:

First, BEVs do not produce greenhouse gases, like CO₂, in the use phase. For an overall assessment of climate impacts of EVs compared to CVs the provision of electricity and other sources of emissions, such as vehicle production and vehicle scrapping, also need to be included. Research shows that the net sustainability effect of EVs is dependent on many factors, such as power generation. The higher the share of renewable energies in electricity generation, the more advantageous the environmental assessment of EVs is (see e.g., Wirges 2016, Stark et. al., 2018).

Second, BEVs show lower noise emissions at low speeds compared to CVs. With low speeds, up to 25 km/h, engine noises are a car's dominant source of noise (e.g., in residential areas, at intersections with traffic lights). In these speed ranges, EVs are more advantageous than CVs as their engine is less noisy. The noise levels of EVs and CVs are similar when driving faster than 25 km/h as the main noise sources at higher velocities are the interaction of tires and road surfaces and aerodynamic noises. However, lower noise emissions might cause negative safety externalities, as it might impair pedestrian safety that is why artificial noise generation are yet increasingly used.

Third, BEVs drive without local exhaust emissions that are hazardous to the environment and health, such as nitrogen oxides and particulate matter. However, EVs like vehicles with other propulsion systems produce emissions by tire abrasion and brakes. However, vehicle production generates local exhaust emissions, both for EVs and CVs. A significant of particular matter is in particular generated in the steel production. As the sources of direct emissions are often taken place in remote areas, those emissions are less relevant to the health of the greater part of the population (BMU 2019).

Fourth, the EV technology is energy efficient. The propulsion system (electric motor) and the transmission system (fixed gearbox) are efficient, moreover idling consumptions (e.g., at traffic lights) are not present.

Fifth, EVs can serve as mobile energy storage in the power grid (i.e., V2G systems) and may therefore provide power grid services. Here, EVs can act either as controllable loads that contribute to leveling the off-peak load by throttling their charging rate (e.g., at night) or they can act as storage devices, for example, when being parked during the day (Guille & Gross 2009).

EVs also have objective disadvantages in comparison to CVs. Those are discussed in the further paragraphs.

First, BEVs are more restricted in their possibilities of car use variation due to shorter driving ranges and longer charging durations compared to CVs.

Second, the purchasing costs of EVs are, due to the current high-battery production costs, in most countries higher than the costs of CVs. However, the recharging respectively refueling costs and maintenance costs of EVs are on average lower than the maintenance costs of CVs as EVs have less and simpler components, less fluids, breaking pads, etc. Hence, if all costs of vehicle usage over the lifespan of the vehicle are considered, EV costs are comparable with CV costs.

Third, an obstacle for the market uptake of EVs is that in the market ramp up phase of a technology, the product is increasingly improving (e.g., in terms of driving range) and also the costs (i.e., production costs and purchase costs) of the product are decreasing with time. In addition, the variation of products available on the market expands gradually over time. Hence, motor vehicles, such as passenger cars are long lasting goods which are not bought on the new car market by many households but on the used car market. Hence in the phase of market uptake, the supply of EVs on the used vehicle market is not sufficient for many potential customers.

Fourth, rare-earth elements (neodymium and dysprosium) and/or critical metals (lithium and cobalt) are needed for the production of the electric motors and batteries, which are predominantly used. With an increased demand in EVs the demand for these rare-earth elements and critical metals will rise as well, and consequently geopolitical issues might impact their availability.

Extensive resource extraction methods (e.g., mining) might lead to air and groundwater contamination in countries with a high-resource density (e.g., China, Chile, Argentina, Bolivia, Congo). Moreover, the resource extraction is emission-intensive. This leads to a global relocation of the EV lifetime emissions to the detriment of countries with a high-resource density (Romare & Dahllöf 2017).

Due to the advantages of the electric motor over the combustion engine, it is the goal of policy makers in various countries to increase the share of EVs in the vehicle stock. In order to support EV diffusion various transport policy incentives can be set. Examples are infrastructure and organizational measures concerning traffic flow (e.g., the permission for EVs to use dedicated bus lanes or high occupancy lanes), infrastructure and organizational measures for stationary traffic (e.g., exemptions from parking fees) and financial incentives on EV costs (e.g., buyer's premium, tax rebate) (Stark et al. 2014).

Activity Space Effects of Electrified Mobility Tools

The electric motor is deployed in two ways for road vehicle concepts: either the electric motor substitutes another motor in the vehicle concepts or vehicle concepts that were originally not motorized are motorized by an electric motor. Both ways have disparate implications to the usage behavior and activity spaces of the users electrify vehicle concepts.

Examples for vehicle concepts with motor substitution are motor vehicles, such as passenger cars, motorcycles, vans, busses and lorries. Those vehicle concepts have, when equipped with a combustion engine, universal possibilities of application. For example, the range of applications includes, but is not limited to, daily commutes, long distance journeys for the summer holiday, shopping, and leisure purposes. The wide range of applications leads to the passenger car not being used the same way every day, but very differently over longer periods of time. If a passenger car has an electric motor instead of a combustion engine, the range of applications might be limited due to range limitations and longer charging durations. However, it depends on the variations in use and applications of the passenger car, the range of the passenger car and the availability and configuration of charging infrastructure whether and to what extent the users are restricted in their travel behavior by the use of EVs compared to CVs.

In terms of passenger transport, diverse population groups have varying and distinct travel needs and activity spaces, which might also differ by transport mode. For example, some elderly might not have the confidence to drive longer distances by passenger car. This also determines whether and under what conditions EVs fit their car usage patterns and mobility needs.

Commercial transport is rather heterogeneous in terms of branches, road vehicle types used and usage patterns. The vehicles used in certain branches, for example, urban distribution and social services, have uniform usage patterns in the longitudinal perspective and are mainly used for short ranges. EVs can be a practicable alternative for these usage patterns. Other branches, for example, logistics, use their vehicles often for longer distances and to transport heavy goods (Frenzel, 2015). Here, BEVs are not applicable. A possible option may be electric trucks powered with overhead lines which are still under investigation.

The electrification of road vehicles for passenger transport, for example, the use of electric busses for public transport or of electric cars for car sharing and ride sourcing, is also an option. A challenge in the deployment planning is that additional charging times and the availability of charging infrastructure must be taken into account (Kley et al., 2011).

Bicycles and scooters are examples of vehicle concepts that were originally not motorized but are now available in configurations with electric motors, for example, pedelecs or e-scooters. Those EV concepts are faster and can be used for longer distances and for the transport of heavier goods than their nonelectric pendants, which are only propelled by muscle power. Hence, they offer new fields of applications, for example, greater trip distances, applications in hilly areas, an interesting vehicle alternative for person groups which do not have the physical condition to use a bicycle over longer distances (e.g., elderly). In commercial transport, cargo pedelecs are suitable to specific branches, for example, delivery services, inner city cargo.

In travel behavior research mobility dynamics, mobility needs and behavior of persons and their vehicle usage are in focus. Research deals, for example, with the market potential of EVs, the substitution potential of CVs by EVs. In order to analyze those issues various methodological approaches are used. A short description of some research methods is given below.

- Stated preference surveys and stated response surveys: survey participants are asked to make decisions in fictive situations, for example, the purchase of a BEV. In order to also account for restrictions that result from the short range of the of EVs, those surveys are combined with other methods, such as vehicle-use diaries. A downside of this approach is that survey participants have often no in-depth experience and knowledge on surveyed topics and products; consequently, they might behave differently in real life situations than indicated in the survey (e.g., Golob, 1990).
- Field trials: EVs are made available to the study participants over a period of several weeks or months and the use of these vehicles is examined in a real life context. A major advantage of these studies is that the use of EVs can be analyzed over longer periods of time. Though, due to the high costs of field trials sample sizes are often small, which might limit the universality and representativeness of the results (e.g., Cocron et al., 2011)
- Cross-sectional travel surveys and data: Cross-sectional travel surveys conducted over one day (e.g., national household travel surveys, available for many countries on a regular basis), are analyzed. The assumption underlying the analysis is that vehicles not used over long distances could be replaced by EVs from a vehicle usage perspective, as EVs do not limit the mobility needs of vehicle users. A drawback of this approach is that the variability of vehicle use is not considered, which leads to an overestimation of the substitution potential by EVs (e.g., Aultman-Hall et al., 2012)

- Car usage surveys and car usage models of CVs over longer periods of time: The underlying assumption for the analysis of longitudinal data is the same as for cross-sectional data; that is, CVs that are not or seldom used over long distances could be replaced by EVs from a usage perspective. However, the variability of vehicle use over longer periods of time is taken into account. For vehicle usage surveys, passive forms of data generation, such as Global Positioning System (GPS) are often used. Another approach to generate vehicle usage information over longer periods of time is the development of vehicle usage models over longer periods of time. Available vehicle usage surveys and other travel surveys serve as input data for those models (e.g., Eisenmann & Plötz 2019).

User Experience and Behavior in Electric Vehicle Usage

EVs come with a number of features that lead to specific, unique dynamics in user experience and behavior. These include the user interaction with range and recharging, the implications of electric drivetrain characteristics for user-system interaction (e.g., bidirectional energy flows and further energy-related dynamics), and the broader implications of EV characteristics for dynamics in user acceptance. The following section focuses particularly on user interaction with BEVs as the most prototypic EV type. Yet, many aspects also transfer to other EV powertrain types that are affected by the dynamics of charging (e.g., PHEVs) or by the partial electric powertrain.

First and foremost, while possibly being a transient phenomenon within the process of mass-market adoption and EV technology evolution, the phenomenon of range anxiety has been commonly discussed as a larger issue of BEVs. Since its first mentioning in scientific literature (Tate et al., 2008) range anxiety, commonly referred to as the fear of becoming stranded with a BEV, has become a widely used term. Yet, empirical user research with actual BEV drivers and psychological theorizing suggests, that the constructs of fear or anxiety do not accurately match the actual range-related user experience in everyday interaction with BEVs. Indeed user experience in situations where the range might not be sufficient to satisfy driver needs is better characterized by constructs such as range discomfort, range workload, or range stress (e.g., Rauh et al., 2015; Franke et al., 2016). Moreover, in everyday usage, drivers actively avoid range stress using available coping strategies like additional recharging, route (re-)planning, or more energy-efficient driving (i.e., eco-driving). In general, drivers thus tend to plan for substantial range safety buffers and do not completely utilize the potentially available range. Hence, psychological theorizing has suggested the concept of three psychological range levels (Franke et al., 2015) which drivers use to manage limited range resources. That is, every limited-range vehicle is characterized by its technical range, meaning the distance it can drive on one charge given certain objectively defined conditions (e.g., driving cycle conditions such as the worldwide harmonized light vehicle test procedure, WLTP). Yet, many psychological factors drive interaction with range. First, competent range reflects the range that users can achieve based on their range management skills (e.g., eco-driving knowledge) and/or based on how easy the vehicle or the environment makes range optimization (e.g., system support for drivers' eco-driving skill acquisition). Second, performant range reflects the range that users usually obtain based on their everyday driving behavior (i.e., eco-driving motivation and habits) and how good the vehicle and environment support and simplify eco-driving (e.g., everyday traffic-related driving conditions). Third, comfortable range is the actual usable range that users utilize with an optimal user experience (i.e., without range stress or range discomfort) based on their perceived coping resources (e.g., available emergency charging opportunities, opportunities and personal skills for extending range) and the perceived accuracy of available remaining range information (e.g., range prediction system). That is, drivers can be expected to develop a preferred range safety buffer over usage, based on their experience with range dynamics (e.g., perceived trustworthiness of range interfaces) and based on personal variables (e.g., technology-related self-efficacy beliefs). Hence, the primary criterion for user-centered optimization of BEV mobility resources is not to maximize technical range but to optimize psychological range.

Structurally similar range management and range experiences dynamics are taking place in drivers of conventional CVs (Philipsen et al., 2019) yet range stress can be avoided much more easily here. Improvements in the total available range and charging speed will obviously limit the likelihood of range stress experiences if users do not heavily change their recharging routines (i.e., negative behavioral adaptation). In any case, designing the range-related users experience (e.g., via optimized user interfaces) is a key task in BEV development.

Charging behavior is closely connected to user interaction with range. Research indicates here that, once drivers have a certain level of abundant charging opportunities at hand (i.e., how many convenient charging opportunities do drivers typically pass before they actually have to recharge to avoid falling below the preferred range safety buffer), they tend to develop diverse charging styles (Franke & Krems, 2013). That is, while some drivers rather tend to recharge whenever possible, other drivers rather tend to recharge only if needed (i.e., based on available remaining range vs expected range demands). Preferred or habituated charging behavior patterns also interact with the issues around the user-centered design of intelligent charging algorithms that aim to increase the efficiency of integrating renewable energy sources into the grid. That is, drivers who charge whenever possible give energy control entities more flexibility to optimize charging processes while drivers who only charge when needed may need a faster recharge providing less time for energy-supply-related charging optimization algorithms.

EVs also come with specific energy dynamics based on the consumption characteristics of electric powertrains and because of the bidirectional energy flow induced by regenerative braking. That is, variations in driver behavior tend to have a particularly pronounced effect on the energy efficiency (and therefore range) achieved in everyday driving. This is the case

for HEVs that have highly complex energy flow dynamics that are difficult to understand for drivers (i.e., resulting in wrong mental models and suboptimal eco-driving strategies in spite of sufficient eco-driving motivation). And it is also the case for BEVs that have relatively simple energy dynamics compared to CVs given their typical single-gear design, yet are still susceptible for wrong mental models because novice BEV drivers tend to neglect the energy conversion losses inherent in regenerative braking thus leading to a biased evaluation of the effectiveness of certain eco-driving strategies (i.e., too positive perception of regenerative braking).

All those specific features of EVs can also have implications for aspects of EV user acceptance. For example, with regard to BEV range preferences, drivers tend to prefer vehicle configuration with much more range than what is needed on an everyday basis. That is, many drivers tend to select range based on more seldom higher range needs unless the BEV is explicitly framed as secondary vehicle, city vehicle or as vehicle for the daily commute which is usually much shorter than the range typical BEVs offer. Further, range preferences can change with practical driving experience leading to dissociations between stated range preferences before vehicle purchase and range satisfaction after more extensive experience.

Summary and Conclusions

This article discusses the role of EVs as a mode of transport. EVs for road use having one or more electric motors and a battery which is charged from the power grid were put into focus. First, the technical aspects of the EV concept were described, such as the various terms and definitions used in the context of EVs, EV architectures and specifications as well as EV charging concepts. Then, the EV concepts were assessed compared to the CV concept and advantages and disadvantages were discussed. Moreover, the activity space effects of electrified mobility tools were described, that is, the fact and subsequent implications that the electric motor either substitutes another motor in the vehicle concepts or vehicle concepts that were originally not motorized are motorized by an electric motor. Subsequently, user experience and behavior in EV usage were briefly discussed, that is, user interaction with range and recharging, the implications of electric drivetrain characteristics for user-system interaction, and the dynamics in users' range preferences.

Given the highly dynamic evolution of electric vehicles, the present article can only provide a snapshot of the currently common technical characteristics, role in the transport system, and usage patterns of electric vehicles. Despite, it seems highly probable that electric vehicles will play a key role in our future transport system.

Introduction: What is Shared Mobility?

Shared mobility—the shared use of a vehicle, bicycle, or other travel mode—is an innovative transportation strategy that enables users to have short-term access to a transportation mode on an as-needed basis. Shared mobility includes various modes and service models and transportation modes that meet the diverse needs of travelers. Shared mobility encompasses a variety of modes, such as bikesharing; carsharing; for-hire services (bikesharing; carsharing); courier network services (CNS); for-hire services [e.g., taxis and transportation network companies (TNCs), which are also known as ridesourcing and ridehailing]; microtransit; ridesharing (carpooling/vanpooling); scooter sharing; and urban air mobility (UAM) (Shaheen et al., 2016a; Cohen and Shaheen, 2016; Shaheen et al., 2017). Active and low-speed shared modes are sometimes collectively referred to as shared micromobility. Table 1 includes definitions of common and emerging shared modes. Common shared mobility service models include roundtrip services (vehicle, bicycle, or other mode is returned to its origin); one-way station-based services (vehicle, bicycle, or other mode is returned to a different designated station location); and one-way free-floating services (vehicle, bicycle, or other mode can be returned anywhere within a geographic area).

In recent years, shared mobility (both passenger and courier services) have grown rapidly due to technological advancements, changing consumer patterns (mobility and consumption), and shifting perspectives toward transportation and vehicle ownership. Shared mobility can help bridge gaps in the transportation network (e.g., facilitating first- and last-mile connections to public transit, offering late-night transportation services, and services scaled for lower-density communities). As such, shared mobility can help bridge gaps in the public transportation network by extending geographic coverage and the service times of transit services. Additionally, more modal choices and a larger pool of travelers can create a “network effect,” where mobility options in close proximity to one another add collective value. Additionally, a growing number of last-mile delivery and courier services are also changing consumer patterns and disrupting traveler behavior. Last-mile delivery services can serve as a substitute for personal trips to access goods and services as consumers take advantage of “just-in-time delivery.” As such, a household’s decision to have goods delivered rather than pick-up goods on another trip has the potential to contribute to notable changes in travel behavior. This article has four key sections. The first section reviews common business models. The second discusses the role of smartphone apps that enable shared mobility. Next, shared mobility’s relationship to mobility on demand (MOD) and mobility as a service (MaaS) is discussed. The final section provides a summary of the article.

Business Models of Shared Mobility

Shared mobility is enabled through four types of common business models, which are based on the relationship of the service provider and consumer. These common business models include: (1) business to consumer (B2C); (2) business to government (B2G); (3) business to business (B2B); and (4) peer-to-peer (P2P) (Shaheen et al., 2016a).

- **Business-to-Consumer (B2C):** In a B2C model, service providers offer individual consumers access to a business-owned operated transportation services such as a fleet of vehicles, bicycles, scooters, or other modes through memberships, subscriptions, user fees, or a combination of pricing models.
- **Business-to-Government (B2G):** In a B2G model, service providers offer transportation services to a public agency. Pricing may include a fee-for service contract, per-transaction basis, or some other pricing model.

Table 1 Definitions of common and emerging shared mobility and last mile delivery services

<i>Service</i>	<i>Definition</i>
Bikesharing (also known as micromobility)	Provides users with on-demand access to bicycles at a variety of pick-up and drop-off locations for one-way (point-to-point) or roundtrip travel. Bikesharing users access bicycles using one of three bikesharing models: (1) station-based bikesharing (users access bicycles via unattended stations); (2) dockless (users may access (unlock) a bicycle and park it at any location within a predefined geographic region); and (3) hybrid bikesharing systems (users may check out and return bicycles either through a station or non-station location). Bikesharing fleets are commonly deployed in a network within a metropolitan region, city, neighborhood, employment center, and/or university campus.
Carsharing	Individuals gain the benefits of private-vehicle use without the costs and responsibilities of ownership. Individuals typically access vehicles by joining an organization that maintains a fleet of cars and light trucks deployed in lots located within neighborhoods and at public transit stations, employment centers, and colleges and universities. Typically, the carsharing operator provides gasoline, parking, and maintenance. Generally, participants pay a fee each time they use a vehicle.
Courier Network Services (CNS)	Provides for-hire delivery services for monetary compensation via an online application or platform (such as a website or smartphone app) to connect couriers using their personal vehicles; bicycles; or scooters with freight (e.g., packages, food).
Drones [also known as Unmanned Aerial Vehicles (UAVs)]	A short-range unmanned aerial vehicle (or UAV) that can transport small packages, food, or other goods.
Microtransit	Privately or publicly operated, technology-enabled transit services that typically use multi-passenger/pooled shuttles or vans to provide on-demand or fixed-schedule services with either dynamic or fixed routing.
Ridesharing (also known as carpooling and vanpooling)	Facilitates formal or informal shared rides between drivers and passengers with similar origin-destination pairings.
Robotic Delivery	Offer short-range unmanned ground-based delivery of packages, food, or other goods using a small conveyance robot.
Scooter sharing (also known as micromobility)	Users gain the benefits of a private scooter without the costs and responsibilities of ownership. Individuals typically access scooters by joining an organization that maintains a fleet at various locations. The scooter operator usually provides gasoline, parking, and maintenance. Generally, participants pay a fee each time they use a scooter. Scooters can be accessed via unattended stations or accessed (unlocked) and returned (parked) to any location within a predefined geographic region. Scooter sharing includes two types of services: (1) Standing electric scooter sharing using shared scooters with a standing design with a handlebar, deck and wheels that is propelled by an electric motor. The most common scooters today are made of aluminium, titanium, and steel; and (2) Moped-style scooter sharing using shared scooters with a seated-design, either electric or gas powered, that generally having a less stringent licensing requirement than motorcycles designed to travel on public roads.
Taxis	Provide prearranged and on-demand vehicle services for compensation through a negotiated price, zone pricing, or a taximeter. Trips can be made by advance reservations (booked through a phone, website, or smartphone application), street hail (by raising a hand or standing at a taxi stand or specified loading zone), or e-Hail (dispatching a taxi driver using a smartphone application).
Transportation Network Companies (TNCs) (also known as ridesourcing and ridehailing)	Provides prearranged and on-demand transportation services for compensation, which connect drivers of personal vehicles with passengers. Smartphone mobile applications facilitate booking, ratings (for both drivers and passengers), and electronic payment. TNCs also includes “ridesplitting,” in which customers can split a ride and fare in a TNC vehicle (where available).
Urban Air Mobility	The safe and efficient system for air passenger and cargo transportation within an urban area, inclusive of small package delivery and other urban Unmanned Aerial Systems (UAS) services, which supports a mix of onboard/ground-piloted and increasingly autonomous operations.

Source: Adapted from: Shaheen et al., 2016a; Cohen and Shaheen 2016; Shaheen et al., 2018

- **Business-to-Business (B2B):** In a B2B model, service providers sell business customers access to transportation services either through a fee-for-service or usage fees. The service is typically offered to employees to complete work-related trips.
- **Peer-to-Peer (P2P):** In a P2P model, service providers broker mobility and courier transactions among car, bicycle, or other device owners and renters by providing the organizational resources needed to make the exchange possible (i.e., online platform, customer support, driver and motor vehicle safety certification, auto insurance, and technology).

These business models are often enabled through a variety of app-based services (e.g., smartphone apps) that provide single-mode access, multimodal access, trip planning, real-time information, and other traveler services.

Role of Smartphone Apps as an Enabler

While shared mobility can be employed independently of technology enablers, such as smartphone applications (or “mobility apps”), app-based services are common enablers of shared mobility services because they increase consumer convenience and facilitate real-time information (and in some cases vehicle or device access). As such, app-based services paired with other

technologies such as GPS, sensors, wireless systems, information technology, big data, data analytics and management systems, machine learning, artificial intelligence, and augmented reality can be key supporters of the shared mobility ecosystem (Shaheen et al., 2016b).

In particular, mobility apps can include a variety of mode specific applications as well as trip planners and multimodal aggregators. Fundamentally, the primary purpose of mobility apps is to assist users in planning or understanding their transportation choices, and they may increase access to a variety of modal options. Increasingly, some apps are using incentives to reduce congestion and encourage sustainable transportation choices. These apps employ gamification to incentivize more environmentally friendly travel modes. Gamification uses game design elements in a non-game context (e.g., badges, levels, leader boards, etc.) to encourage specific types of user behavior. The growing prevalence of smartphone apps is leading to the growth of connected travelers who are more attuned to real-time transportation information and increasingly dependent on real-time information services throughout their journey.

Growth of Mobility on Demand (MOD) and Mobility as a Service (MaaS)

The growth of shared mobility and enabling technologies is contributing to the commodification and aggregation of transportation services. In North America, consumers are commodifying transportation services by assigning economic values to modes and making mobility decisions (including the decision not to travel and instead have a good or service delivered) based on cost, travel and wait time, number of connections, convenience, and other attributes, a concept known as MOD (Shaheen and Cohen, 2019a, 2019b). MOD enables consumers to access mobility, goods, and services on demand by dispatching or using shared mobility, delivery services, and public transportation strategies through an integrated and connected multi-modal network. The most advanced forms of MOD passenger services incorporate trip planning and booking, real-time information, and fare payment into a single user interface. MOD promotes choice in personal mobility, leverages emerging and existing technologies and big data capabilities, encourages multimodal connectivity and system interoperability, and promotes new business models that enhance traveler experience. MOD has three major guiding principles: (1) traveler centric and consumer driven, (2) data connected and platform independent, and (3) multimodal and mode agnostic. In the United States, the US Department of Transportation and Federal Transit Administration are funding pilots and research as part of its MOD Sandbox program to explore partnerships; develop new business models; integrate public transit and MOD solutions; and investigate enabling technical capabilities such as: integrated payment systems, decision support, incentives for traveler choices, and supply and demand management of the transportation network. With MOD, there is a recognition that digital and goods delivery services can substitute for trips, while simultaneously creating demand for new and different trip types. The convergence of MOD with automation is enabling new opportunities for manned on-demand delivery options such as drones, robotic delivery, and automated delivery vehicles.

In Europe, services that allow travelers to sign up for mobility services in one package are gaining popularity. The concept of MaaS evolved approximately a decade ago with an initial pilot in Gothenburg, Sweden known as UbiGo. UbiGo repackaged existing transportation services (e.g., public transit, taxi, bikesharing, and carsharing) into a one-stop, monthly, paid subscription service ranging from \$185 to \$280 US per month for household (including children) subscriptions (Sochor et al., 2018). MaaS redistributes the mobility chain by integrating the products and services of mobility providers and supplying them to users as a single service. Typically, a digital platform creates and manages trips that users can pay for via a single account. A distinguishing feature of MaaS is giving users the option to purchase MaaS products, such as monthly subscription plans that best fit a user's or household's needs. These subscriptions can include a certain amount of each transportation service (e.g., public transportation, bikesharing, carsharing, taxis, etc.) and are similar to other service bundles, such as mobile phone plans, where the user pays one price for the combination of multiple service elements (e.g., talk, text, data, roaming, long distance, etc.). Brokering travel with suppliers, repackaging, and reselling it as a bundled package is a distinguishing characteristic of MaaS. Generally, there is an emerging consensus that MaaS is about integrating multiple transportation modes into a seamless user experience, often necessitating open data and cooperation by public and private transportation stakeholders.

In Europe, some practitioners maintain MOD is a type of MaaS. In the US, others claim that MaaS is one type of MOD, characterizing MOD as a "lower-level" of MaaS based on a five-level MaaS Integration Index. In contrast, the USDOT MOD concept of operations implies that MaaS is a lower-level of MOD because it is a comprehensive approach to transportation systems management, encompassing transportation systems management and operations (e.g., mobility supply-and-demand management) and goods delivery in addition to passenger mobility. With MOD, there is a recognition that every trip has a purpose, and goods delivery may be able to serve as a substitute for some passenger trips (Shaheen and Cohen, 2019a, 2019b).

Fig. 1 compares similarities and differences between MOD and MaaS, drawing upon USDOT's MOD concept of operations. While there are some similarities between the two, MOD focuses on the commodification of passenger mobility and goods delivery and transportation systems management, whereas MaaS primarily focuses on passenger mobility aggregation and subscription services. With MaaS, there is a strong emphasis on information and fare payment integration through a single digital platform. Digital information and fare payment integration, enabled through smartphone apps that are coupled with commodified mobility services, are making traveler options more convenient and seamless through MOD and MaaS. It is important to note that definitions and understanding of MOD and MaaS are evolving. The comparison in Fig. 1 is drawn from the latest literature.

Figure 1 Similarities and Differences of MOD and MaaS.

Summary and Conclusion

Shared mobility is an innovative transportation strategy that enables users to gain short-term access to transportation modes on an as-needed basis for either passenger trips or goods delivery. The advent of bikesharing, carsharing, scooter sharing, TNCs (also known as ridesourcing and ridehailing), and other innovative mobility services is changing how travelers access transportation. The convergence of automation, electrification, and shared mobility will likely transform how people travel and how cities are planned and built in the future. While the impacts of this convergence and other transformative technologies on auto ownership, parking, and travel behavior remain to be seen, policymakers may need to rethink traditional notions of access, mobility, and auto mobility. The advent of shared micromobility and shared automated vehicles enables us to reimagine how we design and interact with cities through street design, curb management, and public policy (e.g., pricing, incentives). The integration of transportation modes, real-time information, and instant communication and dispatch—all possible with the click of a mouse or a smartphone app—have the potential to redefine urban mobility. These changes are contributing to the commodification (i.e., MOD) and aggregation of transportation services (i.e., MaaS). While the impacts of these changes are not fully known, these innovations will likely have a disruptive impact on cities and society in the future. Additional research is needed to understand the longer-term impacts of these innovative and emerging services.

Acknowledgment

The authors would like to thank the American Planning Association, the California Department of Transportation (Caltrans), the Mineta Transportation Institute, and the US Department of Transportation for their generous support of this work. Special thanks also goes to the shared mobility operators, industry experts, and policymakers who make this research possible. Biographies

Susan Shaheen is a Professor in the Department of Civil and Environmental Engineering and a Research Engineer with the Institute of Transportation Studies at the University of California, Berkeley. She is also Co-Director of the Transportation Sustainability Research Center (TSRC) at University of California, Berkeley (UC Berkeley). She was among the first to observe, research, and write about the changing dynamics in shared mobility and the likely scenarios through which automated vehicles will gain prominence. She was the policy and behavioral research program leader at California Partners for Advanced Transit and Highways, a Special Assistant to the Director's Office of the California Department of Transportation, and the first Honda Distinguished Scholar in Transportation at the Institute of Transportation Studies at UC Davis, where she served as the endowed chair until 2012. She has authored numerous journal articles, reports and proceedings, book chapters, and co-edited two books. She has a Ph.D. from UC Davis and a M.S. from the University of Rochester.

Adam Cohen is an innovative mobility researcher at TSRC, UC Berkeley. Since joining the group in 2004, his research has focused on shared mobility, mobility on demand, mobility as a service, urban air mobility, smart cities and other innovative and emerging transportation technologies. He has co-authored numerous articles and reports on innovative mobility in peer-reviewed journals and conference proceedings. His academic background is in city and regional planning and international affairs.

Introduction

Travel information is one of the basic needs of transport users, whether they are car users, public transport riders, cyclists or pedestrians. Information is a fundamental element both in decision making and behavioural change. While full information is rarely available, partial information is key to utilitarian-based decisions in terms of choice set awareness, evaluation of expected outcomes, and monitoring the choice results, thus motivating either habit formation or behavioural change. From the demand side at the individual level, travel information helps people to plan, execute and evaluate their travel choices according to their functional, social and emotional needs. At the social level, travel information aids demand management strategies to increase network capacity, encourage safer and efficient use of infrastructures, decrease carbon footprint and provide more inclusive transport environments for physically and socially vulnerable transport users. From the supply side, travel information increases transport resilience by allowing more efficient planning, detecting cavities and service imbalance, system optimization, real-time service adaptation, event detection, management and system recovery.

Starting from the first decade of the new millennium new low-cost information technologies are inducing a rapid and vast change in the way we see the transport world today. Until the end of the nineties, information gathering and dissemination was expensive, time limited and localized in nature, and thus gathered by transport and local authorities for their planning and operation. The introduction of smart-phones with embedded global positioning systems (GPS), wireless broadband reception/transmission and Bluetooth inter-device communication, have caused a major shift in data collection and dissemination because these technologies allow continuous, real-time and instantaneous passive and active information exchange. Moreover, the induced a shift in the transport information business structure as subsidiary bodies such as phone companies and software development companies serve as data brokers both collecting and selling data to authorities and operators. While some information platforms are of local nature and are financed by public authorities (e.g. 'MinRejseplanen' in Copenhagen), other information platforms have been developed by private sector entrepreneurs and are going global (e.g., 'Waze' and 'Moovit'). Both from the user and operator perspective, smart-phone based data platforms offer three main advantages of direct communication. Firstly, they allow better two-way communication between transport users and operators. Using smart-phones to track the space-time prism of the individual can be tracked over time, can be used for the development of agent-based models for prediction, to provide tailor-based solutions to users and to send real-time notifications to users on system changes. Secondly, these technologies have enabled inter-user communication, thus leading to the formation of transport user communities sharing information, travel resources and services. Last, these technologies have created the possibility for intercommunication between user devices, vehicles and road objects such as road signs and traffic signals.

While information technologies are changing the face of ground transportation, the change is inherently dependent on information technology acceptance, adoption rates, information use patterns and compliance. The main research interests focus on demand evaluation and behavioural compliance. From the business perspective, market demand and penetration rates are essential for understanding the potential market value, product cost-effectiveness and interest of private-sector entrepreneurs in developing such platforms either spontaneously or in collaboration with the public sector. From the transport planning and operation perspective, high market penetration is needed for data harvesting, assessing the potential impact on infrastructure use efficiency, travel time and cost saving, and the reducing environmental externalities.

Existing Information Platforms

Early information platforms provided both static and real-time localized information for a specific location and time frame. With the surge of personalized information and location-based services, and the shift from location-based to user-based information approach, recent studies are focusing on system-wide platforms which provide personalized route-planning solutions. The route

planning solutions allow pre-planning and en-route real time decisions. They display time and cost-based origin-destination route alternatives, as well as traffic congestion and incident alerts. Some route planners provide user-based preference options such as excluding toll route and defining preferred departure and arrival times.

While traditional platforms include information as their sole feature new platforms combine information and service packages relevant to the offered transport services (e.g., car sharing, bike-sharing transit). Examples are route-choice and car navigation apps, parking and car-finding apps, transit information apps, multi-modal information apps, and Mobility-as-a-Service (MaaS) apps. Car navigation apps offer price and time-based route information and suggestions, location information for parking and road services, traffic information, incident and weather alerts, and driver behaviour alerts (e.g., calculated speed with reference to the speed limit). Transit navigation apps provide door-to-door travel information consisting of travel route/line suggestions, walking instructions, transit schedules, alerts regarding service delays and changes, transfer suggestions, walking distances, waiting and arrival times. Bicycle information apps provide information bicycle route planning options, recording journeys and sharing user experience. Multi-modal information platforms provide route planning solutions for cities with multiple mobility services including transit, car-sharing, and bicycle options. Most of the research attention is provided to transit apps and recently to multi-modal apps due to the hope of promoting a shift towards shared and sustainable modes, because statistical evidence shows a positive relationship between information use and transit ridership.

The first generation of travel information platforms are developed on basis of information from service-providers such as local transit and road authorities. The second generation increased user participation in the data collection effort by basing the platform performance also on data harvested and traffic incident alerts from registered users. The new generation of travel information platforms heavily relies on both active and passive user engagement and community champions for map enhancements, service evaluation, traffic congestion estimation, system usage rates and increasing data accuracy and reliability at large. The new generation also supports and promote inter-user communication and collaboration across registered users, both on-line and through meetings and gatherings. Thus, the current travel information world moves from a top-down information provision approach to a collaborative community approach of both bottom-up and middle-out information provision from informal sources in addition to the traditional top-down data resources. An example is the transit information app 'Moovit' which amasses four billion anonymous data points a day to add to the world's largest repository of transit data. Moovit's network consists of more than 450,000 local editors called "Moovitors", who support the data gathering. These users help map and maintain local transit information in cities that would otherwise be difficult to serve. Thus the new age of travel information platforms seek to mobilize communities to engage in travel data gathering efforts. Most information platforms are mode-specific, focusing on car, transit and bicycle travel as separate modes.

Voluntary travel behaviour change (VBTC) elements are starting to emerge as an integral part of the next generation travel information apps. Among these elements are health and environmental feedback, tailoring travel options to specific traveller's needs, tracking for self-monitoring, social networking, nudging and gamification elements. From the user perspective, these elements can be translate into functional gain benefits (e.g., free services, discount coupons and upgrade possibilities), normative benefits of acting in accordance with one's life values and hedonic benefits deriving from the competition/game enjoyment

Information platforms for mobility-impaired transport users form a separate category as an important tool empowering safe and autonomous travel and serve as a cost-efficient, independent and effective alternative to enhancing the urban environment with mobility assistance aids. These platforms are mostly directed towards walking as a main mode and are still at their nascent stage. Thus most of the studies are dedicated to finding the data collection needs in pedestrian environments and facilitating user interface. Among the necessary features uncovered in existing studies are map enhancements with street objects, pavement characteristics, traffic flows, and static obstacles, minimum-barrier route selection, turn-by-turn audio instructions, sending location notifications, communication possibilities with trusted sources such as peer and authorities, voice, vibration and gesture interfaces, image analysis and location exploration possibilities, tagging and collaborative user information exchange. These apps are highly dependent on collaborative voluntary mapping efforts for increasing information accuracy and detecting dynamic changes, and thus user and non-user willingness to engage in mapping efforts through information sharing is an integral part of their success.

Adoption Rates

The full extent of travel information platform adoption and transport information consumption cannot be estimated because such data is not elicited in national or regional travel habit surveys. The developers of the two main information platforms for car navigation and transit information, namely 'Waze' and 'Moovit' publish records of 65 million monthly active 'Waze users in 185 countries and 300 million registered 'Moovit' users in over 2,600 cities in 85 countries. The local mobile application for transit information in Melbourne (Australia) is downloaded more than 4000 times a week. Studies from various regions confirm that travel information is continuously and frequently sought by habitual and occasional travellers alike, in routine and non-routine travel, and for both short and long-distances. Moreover, studies show that information search is an important part of travel for route finding, trip planning and en-route solutions regardless of the quality of the transport system in terms of coverage and level-of-service. A study comparing Copenhagen (Denmark) to Recife and Natal (Brazil) in 2016 found that in both cases the most common sources of information are Google Maps (75.35% in Recife and Natal and 81.6% in Copenhagen) and on-line information (72.11% in Recife and Natal and 93.95% in Copenhagen). A study from Innsbruck and Copenhagen in 2019 add that transit information is that 58% of transit users are interested in level-of-service information (e.g. arrival times, delays, crowding, accidents) and that 41% of transit users are seeking information more than twice a week and additional 22% are seeking information once a week. In another survey in

Copenhagen from 2019, a survey found that 32% of the respondents use car navigation apps frequently, compared with 51% adoption rates of transit information apps and 17% adoption rates of bicycle information platforms. These results echo in other countries. In a survey in China, 77% of the respondents sought transit information at least once a week. In Bristol 57% of the respondents sought information very often for leisure and business trips over 50 miles within the UK, and obtained transit information for unfamiliar trips.

Adoption Motivators

Adoption of new information technologies concerns understanding the functional and psychological motivators for hardware and software technology adoption of advanced travel information services (ATIS). The behavioural models are applied to understand the expected market share (who are ATIS users?), the usage rates (how much, when and where ATIS are used?), the reasons for adoption (Why ATIS is used?) and the impact of ATIS use on mode choice, with transit and bicycle use in particular.

Existing studies are often conducted in relation to the development of new region-specific, mode-specific and service-specific travel information platform prototypes. Hence, in accordance with early information platforms most of the existing studies explain platform adoption for receiving information. Experimental qualitative analysis of small-scale user groups and controlled field experiments are designed to explore the usefulness of specific app features (e.g., weather forecasts) or reveal particular user needs (i.e., mobility-impaired). Adoption intentions and app use are investigated by employing empirical surveys and estimating latent-variable models based on motivational psychology. The explored behavioural models are the Technology Acceptance Model (TAM) and the Unified Theory of Technology Acceptance and Use (UTTAU). The models are technology oriented bringing forward system design, facilitating conditions, user characteristics and social-influence. System design includes perceived information usefulness and quality (performance expectancy) and ease-of-use (effort expectancy) and potential risks related to privacy and data security. The facilitating conditions refer to the transport service climate as well as internet and supporting technology availability and are rarely investigated due to the need for cross-regional analysis. User characteristics include observable indicators of socio-economic and trip characteristics, and latent indicators of attitudes, traits and needs. Social influence refers to visibility and social norms. Among the addressed barriers for travel information platform adoption are: travel information availability awareness, perceived technical difficulties involving hardware (i.e., battery consumption, user interface) and software (e.g., privacy concerns for information collection, secondary usage and improper usage as well as data security issues), trust in the provided information, lack of perceived need and habitual behaviour suppressing information seeking needs. Motivational system features are availability of accurate high-quality information, perceived usefulness in case of disruptions and system changes, hands-on experience and comparison with former travel choices. Individual internal motivation factors include innovation affinity, use of other location- and travel-based services, time-saving skills and perceived importance of efficient travel and environmental attitudes. In existing studies system familiarity is positively associated with information consumption and thus is regarded as a motivational factor in the adoption of information platforms.

Considering collaborative information platforms, a sufficiently large user base and the willingness to share information are essential to the future of collaborative exchange, both for passive and active crowd-sourcing. However, information exchange often exhibits the characteristics of a social dilemma. While the best approach from an individual utilitarian perspective is to use data without reciprocity, the notion of 'free riders' impedes the collaborative data gathering effort. Moreover, daily information sharing is a repetitive 'grey' task with benefits being better information quality and small tokens of appreciation. Understanding travellers' willingness to use transit apps in dual mode, also as data providers, is the new research issue in the new age of collaborative travel apps. A new study from Copenhagen and Innsbruck indicate that 35% of transit users are willing to share travel information with other platform users on occasional basis and another 15% are willing to engage in data provision in a frequent manner. The UTTAU has been employed also to uncover the motivators for information sharing. The strongest motivators for information sharing are social in nature: social norms of sharing, self-actualization associated with helping others and social network engagement habits. Thus the sense of community and information sharing mutually enhance each other because collaborative travel information apps have been found to strengthen the sense of community, social trust and group identity through continuous communication among platform users. Motivators with weaker impact are performance expectancy in terms of information quality and trust in user information, as well as network familiarity facilitating the information provision effort. The perceived difficulty in terms of dedicated time, effort and the need of continuous on-line engagement is a strong inhibitor for information sharing in collaborative travel information platforms.

The acceptance and use of VBTC elements including gamification can serve as 'game changers' in raising the attractiveness of some mobility solutions over others, are potentially powerful in motivating behavioural change and have the potential to induce both benefits and externalities. The effectiveness of VBTC is much researched and is discussed in the next section. A new study in Copenhagen explored adoptions intentions of a travel information platform with integrated gamification elements in order to promote 'green' and 'healthy' travel by producing a modal shift towards bicycle and public transport use. The study investigated normative, gain and hedonic framing motivators by applying the Existence Relatedness and Growth (ERG) theory of human needs. Unlike the UTTAU, which is technology-oriented, The ERG model is anthropocentric, focusing on the ability to satisfy individual needs as adoption motivators. The strongest motivators for using the new travel information platform were gain in trip efficiency improvement and normative reasoning of eco-travel promotion. The two concepts were found correlated with beliefs in trip efficiency re-enforcing eco-travel reasoning. Trust in travel information technology is the third strongest motivator for adoption

intentions of the new platform. Social self-concepts related to environmental activism and to trip efficiency improvements constitute the fourth main adoption motivator. Technical difficulties were found to be stronger adoption impediments compared to privacy and data security concerns.

Adoption and Travel Behavior Change

Compliance with travel information and the ability of information to produce behavioural change is directly related to the provision of effective information solutions associated with increased functional utility and psychological needs. At a first glance, the question is seemingly trivial as additional information may contribute to changes in the travel problem structure and clarify utility gains and losses. In fact, providing traffic and weather information was found to be a trigger for behavioural change already in the end of the nineties with information being radio broad-casted. Nevertheless, behaviour is motivated also by habits, need for control, constraints, perceptions and beliefs that may impede behavioural change both at the single trip level and in the long-term. Additionally, in repeated travel experience, where travel information is supplied on per-trip basis, questions related to the perceived information reliability and regret regarding the non-chosen alternatives may guide short- and long-term compliance. While research is scarce regarding the use of information for planning transit trips and the linkage between seeking transit information and transit use, studies from the last five years show a positive relation between transit information and transit ridership. Studies show that transit information reduces waiting time and its associated stress, and increases transit ridership during habitual travel, occasional trips to unfamiliar locations, and during night. A study from Copenhagen shows that the main motivations for travel information platform use are to save travel time and to seek better alternatives during delays or service changes. In the same study, roughly 30% of the respondents strongly agreed that a multi-modal travel information would help them to cycle more and to use transit and car-sharing more often. A study conducted in Atlanta, Sydney and the U.K. over three years from 2014-2016 show that during a cycling challenge registered users on a smart-phone app cycled 2-3 times more frequently than non-app users. A study conducted in Istanbul, provides evidence that 53% of car users 80% of transit users change their route according to the travel information platform suggestions.

Further Research

Technology use - studies are cross-sectional and focus on adoptions intentions rather than on actual use patterns. An important knowledge gap concerns tracking actual use patterns following the travel information platform adoption. Tracking use patterns will allow a better understanding of the app use frequency, manner and purpose as well as user historical search patterns. While adoption is the first step for app use, the actual use frequency and patterns determines the actual extent of the platform penetration rate, which is necessary for product profitability, sustainability and impact. Secondly, cross-product and cross regional comparisons are lacking and research is focused on the use/non-use of a specific product rather than the choice among various alternatives. Thus, knowledge regarding the relative attractiveness and of design and content features as well as technology engagement motivation is lacking. With the proliferation of the travel information platform market and the existence of both private-sector and public-sector solutions, and the global success of a few travel information apps product comparison is important to determine the actual market share of various solutions.

The digital divide - most of the studies on travel information platforms were conducted in cities with well-developed formal transport systems. More research is needed on app use patterns and information exchange in emerging markets and developing economies with higher degree of service proliferation, lack of service information and dominant informal transport markets. In addition, current travel information systems are designed without consideration of vulnerable travellers. Examples are travellers with mobility and visual impairments, learning disabilities (e.g., Dyslexia, Dyscalculia), elderly, immigrants and asylum seekers. Studies addressing vulnerable travellers will be helpful in reducing the digital divide towards a more inclusive transport information services.

Counter-intuitive choices - an interesting further research question concerns information leading to seemingly counter-intuitive choices, such as trading short-term time savings for long-term healthier choices and preferring collective-efficacy for reaching system-optimum over self-efficacy leading to user-equilibrium. A recent study involving computer simulation of repeated games proposes that travellers can learn how to share simplified road networks in a way that maximizes both personal and societal utility through travel information provision. A stated-preference survey also showed that given demand management explanations increases collaboration with system optimum strategies by 10%. An experiment simulating travel information app use and route choice in a controlled environment show a tendency to comply with the travel information platform suggestions as an anchor to decision making, even in conditions of poor information accuracy. Five case-studies entailing transit use, active travel and safe-driving have shown that gamification can lead to significant proportions of modal shifts towards bicycle and transit use as well as reduce road accidents and fatalities. Embedding these strategies in travel information platforms is the next step. Understanding how these strategies generate long-term sustainable behaviour should follow.

Related services - information apps developed in the private sector are now offering the ability to book transport resources from subsidiary providers, as well as peer-to-peer ride sharing possibilities. New multi-modal platforms of mobility services (e.g., 'Whim') include embedded information regarding the transport solutions. New platforms also offer information about activity, retail and entertainment locations. Investigating mobile payment acceptance and the adoption of related non-transport related services within

the transport information platform is important because these services may determine the platform's lifespan through its attractiveness to stakeholders including private sector investors, collaboration partners and consumers.

Introduction: ICT and Transport Modes

Information and communication technologies (ICTs) are a family of technologies and services used to process, store and disseminate information, facilitating the performance of information-related human activities, provided by and serving both the public at large as well as the institutional and business sectors. Since the 1960s, with the earliest anticipation of the information age, ICTs have attracted the attention of transport experts as the potential new transport mode. In fact, the anticipation of substituting physical movements with virtual movement is even older, as the telegraph and later, the telephone technologies raised similar expectations. As both ICTs and transport technologies facilitate remote activities, there has been much interest in the potential substitution of physical travel by teleactivities. However, with the increasing adoption of ICTs and observation of the penetration style of such technologies it has become clear that, along with its potential to substitute physical travel (which has been lower than expected), ICTs change the transport system and the way we consume it. As such, ICTs are not just a new, virtual transport mode; they have modified the “old” physical transport modes (Mokhtarian and Tal, 2013).

Rapid technological development has exponentially increased the technologies covered under the term ICTs. While until the beginning of the 21st century, ICTs referred mainly to stationary home computers connected to the internet, in the last 20 years, large segments of the population own smartphones, which allow them to be connected to the internet almost anywhere and at any time, and apply a wide variety of software (namely, apps). Therefore it is almost impossible to generalize about the relationships between ICTs and transport behavior, as ICTs are embedded in various devices, activities, and practices and have different relationships with physical activities and travel.

Nevertheless, the extensive and diverse scholarly work regarding ICTs and transportation offers interesting and important insights that go beyond specific technology or application. In the following sections a review of the potential and actual influences of ICT on the transport system is offered, both approaching ICTs as a new transport mode (substitution between physical and virtual activities) and ICTs as modifying the way we use the existing transport modes and perform activities. This paper is organized as follows: the second section considers the potential of ICTs as replacement to the physical transport system, that is, ICTs as a new transport mode. The third section discusses the various modifications of ICTs on the physical system, suggesting that the physical transport system is not replaced but dramatically altered via ICTs, and the last section offers concluding remarks.

ICTs as a New Transport Mode

As the demand for travel is approached as derived demand, that is, derived from the demand for the activities it enables, much of the research regarding substitution between transport and ICTs focuses on different activities and their potential to become virtual, without the costly physical movement. Thus there is large body of research focusing on trips to activities as telecommuting or telework, teleshopping or e-shopping, teleeducation or e-learning, teleconferencing and telebanking. Similarly, organizational activities have also been examined as e-commerce (between firms) or e-governance (between the government and citizens or within the government). The motivation for all “E” and “tele” activities is clear: Instead of spending time, money and other resources traveling to engage in an activity, virtual travel via ICTs is offered.

Since commuting trips are the main contributors to congestion (both of private and public transport), research focusing on substituting telecommuting for commuting, that is, working from home via ICTs, was first suggested in the 1960s. The earliest forecast anticipated significant transportation benefits during the 1980s and early 1990s. During the 1970s it was estimated that in 2000, telecommuting could reduce more than 10% of the total urban VMT (vehicle miles traveled) when fully implemented. However, estimations of the actual impact of telecommuting by 2000 suggest an aggregate impact of less than a 1% VMT reduction (Tal and Cohen-Blankshtain, 2011). While the early expectations for large scale substitution between commuting and telecommuting assumed that most of the workers who *could* telecommute, *would*, and that this would cover all commuting trips, in reality obstacles (both at the workplace and at home) and different personal preferences led to much lower substitution rates and thus to a lower impact on total VMT. Although telecommuting shares have increased over time, telecommuting is mostly partial (i.e., part of the working day) or in addition to commuting trips (i.e., leaving home later, after morning telecommuting). Moreover, since many workers prefer working out of their homes, alternative workspaces have developed, offering shortened commuting trips for all or part of the working week. Thus telecommuting has many facets: working from home part or all of the week, working from home part of the workday, and working from nonhome and nonworkspaces. As a result, the telecommuting impact on the transport system should be measured not only by VMT reduction, but also by its effect on peak hour travel and route choices.

Similar to telecommuting, telescoping or e-commerce was perceived as an activity that would substitute for travel. For shopping purposes, a substitution effect occurs when e-shopping reduces the number of shopping person-trips and/or person-distance traveled. For the most part, when purchases of physical goods are made online, in-store shopping will be replaced by home delivery. Shopping activity is made up of three parts: searching, purchasing, and delivery. Teleshopping can replace all or part of the shopping activity: one can replace physical search with virtual search but continue with physical purchase and delivery while others will replace all three physical activities with virtual activities. Substitution between physical shopping and telescoping can therefore be partial or full, depending on the type of the good, personal preferences and spatial characteristics. Product characteristics affect the potential of online shopping and substitution of different parts of the shopping activity. Books or electronic devices are more suited to purchasing via the Internet than experience goods such as fresh vegetables. Moreover, people tend to buy more expensive products online because of possible larger savings compared with prices in physical shops. Recreational shoppers are less likely to fully substitute shopping compared to functional shoppers, and shoppers with tight time constraints are more likely to replace more physical shopping activities with virtual ones. And finally, spatial characteristics such as accessibility to physical stores by public transport or availability of parking also affect the potential substitution between in store shopping and on-line shopping.

However, various studies have asserted that e-commerce will have a limited or even a neutral impact on the number of shopping trips and distance travelled. This may arise in cases where shopping trips are combined with other activities or when people make multiple purchases during a single shopping trip, and the substitution of e-shopping for only some in-store items does not necessarily decrease the number of shopping trips and will not decrease travel distance.

Nevertheless, e-commerce is growing rapidly. During 2017, one out of five enterprises in the EU-28 made electronic sales, amounting to 17% of the total turnover of enterprises with 10 or more persons employed. In 2017 the percentage of enterprises making e-sales ranged from 8% in Bulgaria to 35% in Ireland, closely followed by Sweden and Denmark (both 32%), Belgium (30%) and the Netherlands (27%).^a In 2019 the total e-commerce worldwide sales are estimated at €621 billion. In the United States, e-commerce sales in the first quarter of 2019 accounted for 10.2% of total sales (\$127.3 billion).^b Against this background it is clear that on-line purchase is increasing steadily and is substituting some in-shop activities. It is less clear, however, *the extent* to which on-line purchases substitute for physical shopping activities and the extent to which it stimulates more consumer activity and thus does not necessarily reduce physical shopping travels.

However, ICTs can affect the location of commercial activities and affect the distance between consumers and suppliers.

Another perspective that is relevant to shopping activities is the supplier side, that is, the extent to which warehouse and commercial chains may replace physical movements with virtual ones (Perego et al., 2011). It was found that ICTs help determine the most time-effective and cost-efficient transportation mode(s) for a given shipment, as well as reduced travel distances as a result of travel optimizations.

Other dominant activities that generate a large share of travel are leisure pursuits, which play an increasingly important role in our daily lives. Their importance has increased steadily over the last 40 years compared with other activities. Part of the growth is due to the increasing numbers of activities that are considered leisure pursuits. In this respect, shopping is not always regarded as a chore; it is frequently perceived as a recreational activity, a pleasant means of physical movement, and as a means of social interaction. Additional leisure activities are social interactions, tourist-related activities and entertainment. Regarding social interactions there are consistent empirical findings indicating that when distance increases, face-to-face contacts are substituted by virtual contacts. Moreover, since time constraints during weekdays are greater than on weekends, virtual social contact substitutes for physical contact during the week, but to a lesser degree during weekends. However, in general, virtual interaction does not replace physical contact, but facilitates it. In other words, ICTs tend to generate physical contacts and do not substitute for face-to-face contacts.

In addition, other leisure activities such as tourist and entertainment related trips do not experienced decline due to virtual activities. The consistent growth in tourist movement suggests that here also, ICTs facilitate and fuel increased demand for tourist activities by presenting places, options, and prices.

^a https://ec.europa.eu/eurostat/statistics-explained/index.php/E-commerce_statistics.

^b https://www.census.gov/retail/mrts/www/data/pdf/ec_current.pdf.

And finally, maintenance activities such as banking, contacts with governmental bureaucracy or other institutions are strong candidates for substitution with virtual maintenance, since many of these activities depend less on the quality that face-to-face meetings offer. Indeed, the growing number of banking services that are offered online, and the fast penetration of these services is well documented. However, transportation scholars have hardly investigated the transport derivative of these rapid changes in banking services, mainly because, at the personal level, banking activities are not frequent and thus have negligible effect on VMT. Therefore although telebanking has substantial effect on the banking system, the spatial patterns of banks and the accessibility to banking services, transport-related research overlooks the potential and actual effects of telebanking on travel behavior. Similarly, e-government activities and their potential to replace physical maintenance activities are overlooked in transport-related research. More empirical research regarding the substitution between physical and virtual maintenance activity and its potential VMT reduction is called for.

While it is useful to examine different activities and their potential for replacement by teleactivities, it is important to acknowledge that at the personal level, engagement in digital activities is often not limited to one activity, that is, people are often involved in more than one teleactivity. It may be looked upon as a digital lifestyle, including various teleactivities that have replaced physical activities, compared with nondigital life style that makes less use of teleactivities. In addition, research that focuses on just one type of activity may be misleading. As [Salomon \(1985\)](#) stresses, “The analysis of total human activity may lead to different conclusions from the analyses of single trip purpose.” In other words, teleactivity may substitute certain physical activities but induce different activities. The overall impact of teleactivities on the transport system does not envision a replacement of the physical system with a virtual one. While ownership and usage of ICTs has increased dramatically over the years, VMT also continues growing and there is no sign yet of reduction or even saturation in physical movements.

Examining the relationships between ICTs and the transport system can be done not only with respect to various human activities, but also with respect to different transport modes. Such analysis raises the question whether different transport modes have different *replacement* potential with ICTs. However, most of the differences between transport modes are manifested in *changing* the use of this transport mode, not by replacing it, as detailed in the next section. One exception is the general expectation that Millennials who use ICTs applications more frequently will have fewer cars and drive less. Although there are evidences supporting it, analysis found that it is largely a manifestation of economic factors (that is, Millennials have less economic resources compared to their parents in their age) and not necessarily a structural change ([Klein and Smart, 2017](#)).

ICTs as Modifiers of Existing Transport Modes

As the previous section demonstrates, approaching ICTs as new mode of transportation captures just part of its impact on the transportation system. ICTs potential to replace physical transport modes is limited, and empirical evidence suggests that in most activities, substitution between physical and virtual activity is less than expected. However, there is consistent empirical support for the claim that ICTs modify the transport system both through direct impact on the transport system, or indirect impact on spatial and temporal activity patterns.

Direct Impact: Intelligent Transport Systems (ITS)

ICTs are at the heart of the development of an intelligent transportation system (ITS) that supports the physical transport system and enables its more efficient use, coined often as “smart mobility.” ITS can be divided into two categories: intelligent infrastructure systems and intelligent vehicle systems. The ultimate product of ITS is the combination of the two, intelligent vehicles that are connected to intelligent infrastructure that reduce human involvement in driving, leading to automated, autonomous connected vehicles. However, while autonomous vehicles are still not operating in the market, many ITS components are already part of the transport system, with significant impact.

Intelligent infrastructure systems are often concerned with the operational perspective. They offer smart systems for parking management, toll roads, public transport operation, coordinated freight transport systems, firm logistics and road management. The use of ICTs in transport operation increases system capacity, increases its efficiency by means of operation costs and level of service and enhances its reliability. In other words, instead of replacing the physical transport system, ITS enables better use of the system, therefore, enabling more physical movements.

On the other hand, intelligent vehicle systems are personal devices that enable travelers to adapt to road condition, avoid congested routes, park their cars with a higher degree of certainty and use public transport more efficiently. With the substantial development in ICTs and related sensing technologies, new vehicles are equipped with vehicle automation and communication systems (VACS) that can improve individual safety, comfort, and convenience as well as having the potential to develop global traffic efficiency through traffic control.

Using ITS at the personal level reduces travel (in private and public transport) and parking costs, and therefore may have a positive effect on the demand for travel.

The distinction between infrastructure and vehicles is becoming blurred with the emergence of technologies that connect vehicle and infrastructure and the use of big data that have made it easier and cheaper to collect, store, analyze, use, and disseminate multisource data ([Sumalee and Ho, 2018](#)). Vehicle-to-vehicle as well as vehicle-to-infrastructure connections enable more informed and manageable transport systems that can react in real time to expected and unexpected incidents, optimize system usage and better inform its various users. As both intelligent infrastructure systems and intelligent vehicle systems improve the capacity and

usefulness of the transport system, it may be concluded that an increase of physical movements can be accommodated, contradicting the expectation of replacing physical movements with virtual ones.

Freight movements attract special attention within ITS applications. Developments in the field of freight resource management, freight and vehicle tracking and tracing, and front or back-office logistic systems have dramatically improved freight movement and supply. There are numerous types of city logistic schemes that have either already been implemented or are proposed: advanced information systems, cooperative freight transport arrangements, public logistics terminals, load factor controls, and underground freight transport organization. As the share of goods movement in total kilometers increases over time and its presence at the transport system become more dominant, the importance of efficient freight movement increases as well.

Indirect Impact: Modifying Spatial and Temporal Behavior

ICTs not only change our travel mode, they also change our activity patterns. This means that we approach activities differently and perform the activities in different places and at various temporal opportunities. First, ICTs may have temporal and spatial effects on our physical travel, that is, they may facilitate peak-hour avoidance or congested routes by changing departure time or work location. Second, and related to the first, ICTs encourage fragmentation of activities, enabling activity performance at various locations during the day. And third, ICTs intensify multitasking, that is, performing more than one activity simultaneously. As a consequence of activity fragmentation and multitasking, ICTs affect our travel utility by enabling performance of useful, productive activities while traveling, compared with previous conceptions of travel time as waited time.

Temporal and Spatial Modification of Travel

Research has identified several modifications in travel patterns that have resulted from ICT usage as ICTs increase flexibility and open more opportunities for coping with space-time constraints. First, ICTs may affect the length of trips, both shorter and longer trips. Those who choose to work from offices closer to home in places offering temporal working spaces, (all or part of the week) will have shorter commuting trips. On the other hand, those who choose to work from home may move to live further from their workplaces so that, when working from the office, they will have longer commuting trips (though this may be offset by nondriving on days of telecommuting).

Second, ICTs can modify trip routing and destination. This may be a result of real-time estimation of traffic congestion delivered by various applications (like Waze or Google Maps) or ICT facilitation of microcoordination, such as redirection of trips that have already started, by contacting other people during travel and changing the place or the time of a planned meeting.

Third, ICTs may affect the timing of physical travel, especially avoiding peak hour trips, if one chooses to work from home in the early morning, and travel to the workplace after morning peak hours.

Fragmentation of Activities

In contrast with efforts to quantify the total effect of ICT on VMT, scholars have identified the importance of day-to-day management of activities and movements, that is, examining the role of ICTs in the distribution of activities across time and space during the day. As Hubers and her colleagues define it, “activity fragmentation implies that a certain activity becomes divided into several smaller components, which can each be performed at different times and/or locations” (Hubers et al., 2018, 94) and have identified three aspects of fragmentation: the number of fragments, the duration of each fragment and the temporal and spatial distances between the different activity episodes and locations.

ICTs relax the ties between location and activities that are taking place, thus enabling division of activities between locations in a way that better fits personal time needs. For example, working activity that used to be constrained to the workplace (spatially) and during working hours (temporally) can be divided into a morning session at home (e.g., reading and responding to e-mails between 07:00 and 08:00), a traveling session (e.g., a phone discussion with a colleague while driving between 8:30 and 9:00), a workplace session (e.g., meetings between 09:00 and 16:00) and an afternoon session while waiting outside your child’s ballet class (e.g., finalizing a written document between 17:00 and 18:00).

In the same vein, other, nonwork activities can be fragmented more easily with ICTs. Shopping activities can be in-site but also remotized, depending on the place and time of activity, as well as education, maintenance or social relationships. Since fragmentation means that there are episodes of activity that are spread along time, we can see maintenance activities during working hours, or shopping activities during studying hours. The spatial independence of certain activities loosens space-time constraints and compensates for more rigid time or space activities by enabling episodes of other activities when location and time are not flexible.

Fragmentation of activities facilitated by the proliferation of ICTs may have bi-directional consequences for the transportation system. On the one hand, it may encourage movement, as the cost of replacing locations declines when they have less influence on the activities employed. On the other hand, it may reduce the motivation to move and replace locations, since at the same location we can be engaged in various activities, and adjust the activities to time constraints, and that may reduce travel. But the consequences of activity fragmentation go beyond the transport system. Fragmentation and as a result, a mixture of activities and diminishing borders between work, family or leisure activities have wider societal influence, affecting the relative weight of the different activities undertaken and our well-being.

Travel-Based Multitasking

Performing multiple activities simultaneously is referred as multitasking. Specifically, travel-based multitasking is the performance of additional activity while traveling. Scholars distinguish between active and passive activities, that is, travel can be active (as a driver) or passive (not driving) and the other simultaneous activity can be active (reading, talking on the phone) or passive (sleeping, daydreaming) (Circella et al., 2012).

Most empirical studies on travel-based multitasking have focused on public transit passengers, reflecting the fact that transit passengers are the most likely travelers to engage in travel-based multitasking, since they are passive travelers. Bus and rail transit riders, in particular, have benefited from ICT developments that have offered growing number of potential multitasked travel activities. A small (however increasing) number of studies have analyzed travel-based multitasking across multiple transportation modes. Multimodal studies demonstrate that travel-based multitasking is relatively common across all modes, and some activities are more suitable to performing privately and not while using public transport (e.g., talking or eating). Active or passive traveling affects the additional activities that are performed. Car drivers are more likely to be listening to music or other audio. Passive travelers, on the other hand (public transport users or car passengers) tend to read, write, rest, or sleep. In addition, travel-based multitasking appears to increase with travel time.

Multitasking attracts transportation scholars' attention mainly since it may affect the perceived travel time costs, as portable ICTs may influence travel decisions by making travel more productive and therefore, not a complete waste of time. As multitasking during passive travel offers more opportunities for simultaneous activities, multitasking is often considered a tool to promote public transport usage. It suggests straightforward policy implications: public transport should accommodate travelers' additional activities (such as offering wi-fi connection, electrical connection, shelves, or adjusted tables) in order to attract travelers to public transport and increase their utility from the travel (Hong et al., 2019).

Summary and Conclusion

After more than a half century of extensive empirical research regarding possible relationships between ICTs and physical movements, scholars agree that no straightforward, simple relationships can be identified. Those relationships vary across activities, technologies, personal preferences, and life situations. Currently, the expectation that ICTs would be the new mode of transport and replace the physical one has not materialized. Indeed, the use of ICTs has increased dramatically and is expected to continue with its rapid penetration. However, the use of physical transport is not declining; on the contrary, VMT continues to grow and physical movements are still a central part of our everyday lives. However, it may well be that ICTs replace certain activities, at least partially, and by relaxing our travel budget, they enable addition of new physical trips with higher value. Thus although the total VMT is not affected substantially, the composition of our travel has been altered via ICTs-based activities.

Although the expectation for substitution between virtual and physical activities has not taken place, ICT impacts on travel behavior are no less than dramatic. ICTs have modified the transport system both directly via ITSs that are embedded in vehicles, infrastructural personal equipment, and organizations active in the transport system, and indirectly via changing our tempo-spatial activity patterns, simultaneous activities and utility from time spent traveling. ITS increase the efficiency of the transport system and its capacity, thus may encourage more physical travel. Modification in our activity patterns on the other hand may increase physical movements, but in other cases it decreases physical transport usage. The implication of modification of activities pattern goes beyond the transportation system, it affects productivity of the working force, consumption patterns, career and family life, life satisfaction and personal and social relationships, to mention a few. Thus, ICTs should be approached not as a merely new transport mode, but as technologies that modify human perception, activities and human interaction, and therefore, the general urban metabolism.

Biography

Dr. Galit Cohen-Blankshtain is a senior lecturer at the Department of Geography and the School of Public Policy at the Hebrew University, Jerusalem. She earned her PhD from the Free University of Amsterdam and spent a year as a Post doctorate fellow at Harvard University, Kennedy School of Government. Her main research interests regarding public policies in various filed as transport, urban policy, and environmental policy, as well as public involvement in policy processes. She is interested at policy processes and examining different societal, institutional, and political aspects of transport policy and the interaction between policy and community.

Introduction

Dynamic approaches to travel behavior have emerged over the past decades that aim to investigate mid- to long-term behavioral change over time. Some of this research looks at the effects of voluntary travel behavior change campaigns on mode choice to evaluate policy programs. Other studies shed light on the development of travel behavior throughout people's life courses. They use labels such as "mobility biographies" or the "life course approach to travel." While these two strands are closely related to one another, this chapter is situated in the mobility biographies literature (Lanzendorf, 2003; Chatterjee and Scheiner, 2015; Clark et al., 2016; Rau and Manton, 2016; Scheiner, 2018). The reasoning behind studying travel behavior change under the notion of the life course or biography is because behavioral changes typically end up in the formation of new routines and therefore may have long-term consequences. What is more, they are embedded in wider social, economic, and spatial settings that are stable in the long-term. Thus, the evolution of travel behavior over time can be seen as an interplay between stability and change.

Mobility biographies research to date has strongly focused on estimating the effects of life events on travel and, more specifically, mode choice, although the approach is much broader than this may suggest. This chapter provides an overview on the role of life events for mode choice change and puts this into a wider perspective of theoretical ideas that are relevant for mobility biographies studies.

The chapter is structured as follows. The next section presents basic ideas of the mobility biographies approach. This is followed by an overview of the empirical work done on the effects of life events on travel. The subsequent section theorizes the emergence of stability and change in mobility biographies, including different levels on which change and stability may occur, the factors that contribute to resistance to change and to triggering change, and the role of socialization in this respect. The paper closes with a summary and conclusions.

Mobility Biographies—Basic Ideas

The mobility biographies approach makes use of the basic ideas of travel theory and aims to develop a life course-oriented, dynamic framework. Life course and biography research have a rich tradition in various disciplines. Time geography provides an important point of origin for mobility biographies, as the life course can be seen as a special kind of space-time path, as developed by time geography. Time geography also inspired early work in the 1980s that categorized travel behavior by life cycle stages. The life cycle perspective was later applied in dynamic transport models such as MIDAS or ALBATROSS.

Mobility biographies studies have closer links to life course research than to biography research. The life course is typically conceived as a sequence of events and role transitions that a person lives through from birth to death. In contrast, a biography is understood as a subject's self-reflective, meaningful action within the temporal structure of his or her own life. Accordingly, life course studies attempt to record and analyse stages and sequences in people's lives that are separated by transitions typically defined by discretionary events. This is also what the overwhelming majority of mobility biographies studies to date do (e.g., Scheiner and Holz-Rau, 2013a; Oakil et al., 2014; Scheiner, 2014; Sharmeen et al., 2014; Zhang et al., 2014; Klein and Smart, 2019). On the other hand, biography studies tend to reconstruct the subjective meanings someone associates with his/her own life. Only relatively few

mobility biographies studies fall into this category (e.g., [Rau and Manton, 2016](#); [Plyushteva and Schwanen, 2018](#)). The term mobility biographies itself was only introduced after the turn of the millennium ([Lanzendorf, 2003](#)) when similar ideas were developed in various places around the world, with a nucleus in central Europe.

A number of key concepts in life course studies have been utilized in mobility biographies studies. The central idea is that lives can be understood as temporal paths or trajectories, and any point on such a path is a consequence of past experiences and decisions made, as well as of future expectations, anticipations and aspirations. The paths are structured by life stages (or phases) that are characterized by social roles and statuses, and their combinations (e.g. employed father, student mother). Changes in social role or status are called transitions, and go along with life events (e.g., entry into school, marriage), also called life course events, or key events.

With respect to interrelations between various decisions made in a life at a certain stage, a hierarchical structure between long-term, mid-term and short-term is commonly assumed, in which long-term decisions shape the conditions and options for future decisions. For instance, long-term residential choice is typically assumed to shape mid-term vehicle ownership choices, that in turn shape short-term daily travel choices ([Lanzendorf, 2003](#)). Suffice to say that reverse relationships may occur on all levels.

Five major elements can be identified that play a key theoretical role in the mobility biographies approach ([Scheiner, 2018](#)). Each is discussed in more detail as follows.

1. **Societal embedding:** Though individual in nature, life courses develop within a societal aggregate. Hence, mobility biographies need to be understood in a wider context of historical circumstances and processes in time and space. This is why they may be cohort specific, rather than universal, and may even be specific for certain sub-groups within a cohort, for example, for men or women. This suggests that different levels of development (society, interpersonal relations, individual . . .) need to be distinguished.
2. **Habits:** Habits are reflected in the routine character of daily travel. They are automatic, non-deliberate behaviors that result in strong behavioral stability over time. Habits are a powerful, but not the only, factor that counters change.
3. **Linked-life domains:** Close relationships exist between individual mobility biographies and other domains of the life course, such as housing, family/household, employment, social networks, health, lifestyle, and even religion.
4. **Life events and learning processes.** Significant changes in mobility are motivated by transitions, events and learning processes over an individual's biography, and associated breaks in routines. A large portion of empirical mobility biographies work focuses on the impact of life events on mode choice and car ownership. The events may be deliberate choices, foreseeable but unavoidable events, or unexpected events that are beyond the control of a person or household. They may be directly related to the life course in terms of a person's private or professional career, or not (such as an accident, or an exogenous, targeted or non-targeted intervention into the transport system). Longer-term, gradual processes have been less studied. They may be due to learning processes and experiences made, as well as changes in needs and aspirations induced by gradually changing life situations, such as declining health status in higher age.
5. **Socialization:** There are links between someone's life course and the life courses of others in their social environment. These links may be studied using terms such as "linked lives" or socialization. As the mobility biographies approach has been developed as an individualist approach, this point has attracted relatively little attention to date. It suggests strong links to recent research on the role of personal social networks for travel including both intra-household (or intra-family) and extra-household interactions. For instance, an individual's mode choice may not only change when this individual retires, but also when her partner retires. What is more, socialization also links the individual to his/her wider social environment and is expressed in different levels of change.

Life Events—Empirical Work

The events that have been studied with respect to their relevance for mode choice include a broad range that can be classified into three categories to a large extent:

1. **Household/family biography:** leaving the parental home; formation of a household with the partner; the birth of a child (first- or higher-order); divorce/separation; move-out of a child
2. **Educational and employment biography:** commencement of job training or university entry; entry into the labor market; change of job, workplace location or education; entry into unemployment; retirement
3. **Spatial mobility:** gaining a driver's license; purchase or disposal of a car or other 'mobility tool'; residential move.

This is of course by no means a full list of possible events. For instance, changes in health status or accidents have received relatively little attention to date. Also, daily life in families with children has its turbulences and sometimes seems to be filled with virtually a continuous succession of events. What is more, the definition of an event and its hypothesized effect on travel strongly depends on whose mobility biography is studied when several people are affected by an event. For instance, when a couple with a teenage child separates, this may affect the father's, the mother's and the adolescent's travel in very different ways.

Some existing studies work with secondary data (e.g. national travel panels) and, thus, the choice of life events tends to be driven by data constraints. But even in targeted surveys it may be difficult to capture rare or unexpected, but possibly significant events (e.g., the purchase of a household dog). Another criterion for the selection of events is motivated by the strong representation of planners

and geographers in this research. Both groups are typically interested in changes in accessibility and the built environment. This may be the reason why moving home has been the life event that has probably been researched the most to date (Scheiner and Holz-Rau, 2013b; Zhang et al., 2014; Lee and Goulias, 2018). The reason why residential relocation can be expected to affect travel behavior is because access to opportunities is likely to change. Such opportunities include activity places like the workplace, shopping and leisure facilities, and transport provision. This suggests that two features of relocation are important (Scheiner and Holz-Rau, 2013b; Chatterjee and Scheiner, 2015).

Firstly, the combination of the pre-move home location and the post-move home location is of great importance, as a change in accessibility is as much influenced by neighborhood/location attributes at the former place of residence as those of the new place. Secondly, distance of the move needs to be considered, as it indicates the extent to which existing activity places can be maintained after the move. Long-distance migration might lead to more long-distance travel to visit relatives, whereas the former workplace is not likely to be maintained (in many cases a workplace change will have triggered the long-distance relocation). In double-income households, relocating closer to the workplace of one partner might lead to longer commutes for the other. It should be noted that home moves often coincide with other life events such as the birth of a child or workplace changes.

With respect to outcomes, research has shown that moves from inner cities to suburbia tend to be followed by increases in car use and decreases in public transport use, cycling and walking. The opposite is true for relocations into the city (Scheiner and Holz-Rau, 2013b). The changes may be stronger for car and public transport than for cycling and walking, but are contingent on geographical context. Other studies found less change in mode choice after relocating, particularly in places where people heavily rely on cars irrespective of residential location.

Concerning other life events, results are mixed (e.g., Scheiner and Holz-Rau, 2013a; Scheiner, 2014). Birth of a child tends to be associated with an increase in car ownership, driving and walking (the latter being more true for women than for men). Founding a couple household tends to increase car use as a passenger, suggesting shared trips. Entering the labor market tends to result in more driving and less trip-making as a car passenger, on foot or by bicycle, suggesting tighter time budgets and increasing income. Generally, the effects of life events on general mode choice appear modest, and they vary widely between individuals. They may be somewhat stronger when more specific travel indicators are studied, such as commute mode. Significant effects on changes in mode choice have also been found for baseline variables (such as household composition and urban context) (Scheiner and Holz-Rau, 2013a). This may reflect continuous adaptation to changing circumstances or/and lagged responses to life events. Some direct evidence of anticipated (lead) and delayed (lagged) effects of life events is also available (Oakil et al., 2014).

Two events that have been found to be most influential relate to acquiring the means for mobility (or “mobility tools”): a driving licence and a car. These could be regarded both as life events that affect mode choice (“independent variables”) or dimensions of travel itself that are influenced by (demographic, socioeconomic, or environmental) life events. Both events may be understood as relatively stable pre-decision characteristics of mobility.

Taken together, changes in car ownership and mode choice seem to be more common among those experiencing life events than those who do not. As travel variables are typically used as the outcomes in related research, it is less clear whether car ownership or mode choice decisions have an influence themselves on future life development, such as economic or social integration. An exception are studies on the elderly that tend to find that driving cessation results in negative well-being, although the results are inconclusive (Scheiner, 2006; Chihuri et al., 2015).

Understanding Stability and Change in Mobility Biographies

Sorting Levels of Change and Stability

Distinct levels of analysis can be identified in the literature on theories of change, with authors either focusing on individual (behavior, attitude) change or on systems change (system transformation, macro social change). In between these two extremes there are theories of organizational change that typically look at enterprises or administration. Individual travel behavior change is the main interest of mobility biographies research, though interactions with other individuals, as well as organizations and societies, need to be taken into account. Looking at the span between individual and societal levels, a classification of theories may be as follows.

1. Individual level theories. These theories include “classical” psychological theories that are largely limited to the individual.
2. Interpersonal behavioral theories. These theories include focus on the role of interactions, social embedding, role models, or mentoring.
3. Community theories of behavior. Such theories relate to groups, organizations, social institutions, and communities.
4. Systems transformation theories. They relate to society, politics or/and the economy on the national or global level as a whole.

This chapter cannot discuss all these theories in detail. It is important, however, to be clear that the different levels must be linked. There cannot be communities or organizations without individuals, but on the other hand individual action cannot be adequately understood without taking into account the organization of individuals in social groups and economic, administrative and political institutions. This can best be described as a reciprocal relationship. The links may be shaped in myriads of ways, and they are on multiple levels, not just on two or three.

Resistance to Change

Before turning to change it is important to understand why mode choice appears to be quite resistant to change over time. The most widespread theoretical concept used to explain why behavioral change may not occur is habit. People develop habits based on internal scripts which they automatically retrieve to reproduce action without much effort. Habits work as behavioral “recipes” or behavioral rules that can easily be applied in situations that are experienced as similar to other, previously experienced situations. Habits result in a simple form of path dependency—a good predictor of someone’s behavior tomorrow is his/her behavior today. (Manifest) habits are visible in repeated, routine behavior. Conversely, however, repeated behavior does not in itself provide evidence of habits being at work. People may repeat their behavior because they have found an individual optimum solution and have no reason to change.

Habits resemble the idea of heuristics (or shortcuts) in that they work as behavioral “recipes” to reduce complexity and uncertainty. Heuristics are however not necessarily linked to “automatic” behavior, such as habits, but may be used in a conscious, “controlled” way. Travel behavior is a very complex form of behavior, and heuristics are simplifications of situations. They are stereotypically applied as long as they practically work, irrespective of whether or not the information processed meets reality. As such, they tend to stabilize behavior, rather than contributing to change. When applied in slightly varied situations in which behavior meets unexpected reactions (e.g., following a life event such as residential relocation), precisely the application of heuristics may result in change. On the other hand, in exactly such situations circumstances may prevent people from using “recipes.” This may motivate them to develop new or revised heuristics.

The use of habits and heuristics are relatively universal ways of acting. Resistance to change may also be a personality trait that is specific to some people, but not all. Risk aversion and aversion of regret that may occur in traveling due to choices made under uncertainty (e.g., one does not know whether an alternative mode or route is as beneficial as it appears) may lead to “choice inertia,” that is, resistance to change. Similarly, resistance to change may be caused by threats to an individual’s identity. This is when identity is constructed around symbols (e.g., a car), beliefs or activities associated with a particular behavior (e.g., driving). Also, lack of self-efficacy can cause resistance to change when someone does not believe that (s)he is able to achieve behavioral change or the desired outcomes.

A final, perhaps most important obstacle for mode choice change is lack of motivation. Even in the case of pathological behaviors (e.g. drug abuse) strong patient motivation and incentives are needed to achieve change. Mode choice is not pathological but rather has strong rational and normative foundations. This points to one of the major shortcomings of applying voluntary change policies in the transport or sustainability sector. It is questionable whether strategies such as education, information, reminders or prompts can be incentives as long as there is no suffering on the individual level. The ‘suffering’ in mode choice is mostly on the societal level, while on the individual level travel choices are the outcome of reasonable considerations made under certain circumstances and needs. In terms of protection motivation theory: someone may be convinced of being capable of behavior change towards sustainability (high self-efficacy), but it is unlikely that (s)he is convinced that his/her behavior change substantially affects sustainability in general (low expectancy of threat decrease). The individualist rationality in mode choice also highlights the importance of the quality of the choice alternatives. If people are provided with, say, free public transport tickets, and opt to use them but learn that public transport fails to satisfy their needs, they will hardly become permanent public transport customers.

Last, but not least, it shall only be touched upon here that persistence of behavior can also be due to a higher, system level that prevents change, as multi-level transition theory argues. The concept of regimes has been used to understand the forces that prevent change on these higher levels of political, economic, or sociotechnical systems. This has mostly been discussed in transition theories, but less so in micro-level theories such as the mobility biographies approach.

Triggering Change

The most frequently researched idea in mobility biographies studies is that changes in social role or status and associated life events trigger change in mode choice. This idea suggests that different life domains are linked to travel changes, as life events are typically linked to one or more domains other than mobility. This may result in another form of path dependency. Long-term travel evolution may be the outcome of choices made in another life domain, for example, car dependence based on residential choice. However, these considerations do not answer the question of *why* life events affect travel.

It can be argued that life events (or their anticipation) change people’s life situation, social roles and, sometimes, conditions for mobility. Habits do not work anymore because travel requirements, opportunities and/or abilities (“ROA model”) may have changed (Busch-Geertsema and Lanzendorf, 2015). Travel behavior is reconsidered, and deliberate decision making becomes necessary. An important conceptual trigger in this respect is the emergence of stress (Clark et al., 2016). The theoretical mechanism is that life events produce a discrepancy between current needs or aspirations (e.g., for car ownership) and actual (car ownership) state, and this discrepancy produces stress, imbalance and reassessment. Finally, either attitudes or behavior (or both) will be adjusted.

It may be important to note here that transport researchers tend to highlight the adjustment of behavior as a result of such stress. However, the attitude-behavior link has never seriously been conceptualized as a unidirectional link. Rather, stress may be reduced by adjusting attitudes to existing behavior, and this way of adjustment is probably more common than the adjustment of behavior to pre-defined attitudes (Kroesen et al., 2017).

In order to develop behavioral intentions and, ultimately, change behavior, people need to be motivated. Hence, there is a need to introduce motivation and the question of how motivation changes into theories of behavioral change. On the other hand, motivation alone would not drive action if there was no expectation of success. The term self-efficacy captures whether someone expects to be able to successfully perform certain behavior. Similarly, the theory of planned behavior, that has been used frequently in transport studies, includes perceived behavioral control as a predictor of behavior (mediated by behavioral intention).

The Role of Socialization in Stability and Change

Individual life courses are not isolated from other people's life courses. They are embedded in social structures on the personal level, in family, kin, friendship, and neighborhood networks, as well as in economic, political, or administrative organizations. The term socialization refers to the integration of individuals in the society over the course of their lives by means of learning from significant others who work as socialization agents. Socialization has been proposed as a mechanism through which social norms regarding behaviors are transmitted to someone being socialized via these agents. Socialization may also be understood as mutual interaction that enables group integration. This may refer to a small group, such as a family or a clique, or society as a whole. Typical socialization agents are parents and the family, peer groups, media, or schools (Döring et al., 2019).

Socialization is not limited to childhood and adolescence (although these are the most formative stages), but rather spans the whole life course. The knowledge, pre-dispositions, attitudes or behavior that is transmitted are 'the normal' that needs to be known or done to be part of the group. Mobility socialization is thus the process of transmitting mobility as a norm, and this process makes the individual part of the mobile society.

Socialization thus typically works against change in the aggregate. It might be understood as sort of a "habit on the aggregate (or system) level." This may be a major obstacle to implementing voluntary change. To take an example: Why should someone stop driving while most others around him or her continue to do so? On the other hand, if someone feels that his or her behavior represents only a small minority, (s)he may adjust to the majority and, thus, change. For practical applications this means that if a concept succeeds in changing many people's behavior, it is likely that even those who strongly resist changing may finally adapt.

There is evidence for the impact of parents, spouses, schools, neighbors, collective urban mobility cultures, cohorts, and earlier peer groups (e.g., mobility cultures at previous places of residence) on mode choice. This research generally finds positive behavioral links, suggesting that conformity in behavior predominates over non-conformity (Sunitiyoso et al., 2013). This suggests that socialization is a powerful force that may inhibit mode choice change following life events. However, over and above behavioral correlation, the idea of mobility socialization presupposes that mobility is a relevant phenomenon for group integration; otherwise there would be no pressure to adjust mobility. Experimental results suggest strategic behaviors that follow other group members and conformity to the majority choice, and this suggests socialization has a stabilizing function (Sunitiyoso et al., 2013).

Summary and Conclusions

The mobility biographies approach and, more specifically, research on mode choice changes as a result of life events, has grown into a substantial research field. Psychological and sociological theorizing helps understand why these changes may occur, but also why mode choice may be stable in the long term, even notwithstanding massive changes in someone's life circumstances.

Perhaps the biggest obstacle to applying models that have their roots in psychotherapy to mode choice change is that there is typically little individual suffering in mode choice (as opposed, e.g., to drug abuse). Hence, one may ask where motivation for change should come from. The theoretical mechanism that links life events to mode choice change is stress. Life events may produce a discrepancy between current travel needs and actual state, and this discrepancy produces stress and reassessment and, perhaps, behavior change. However, people need to feel able to change, and they need to have some expectation of benefit in order to start a behavioral change process.

Some broad key issues that may be highlighted as steps forward in the mobility biography literature are as follows.

1. *Develop and test theories.* This chapter has touched on multiple theoretical concepts that may help understand behavioral stability and change over the life course, including habits, motivation, attitudes, expected benefits, self-efficacy, and the interaction of individuals with close others, as well as with the wider social, economic, and spatial environment on various levels. These ideas need to be elaborated upon in more depth to integrate them into a mobility biography framework.
2. *Link quantitative and qualitative approaches.* There is a general focus on quantitative studies in mobility biographies research, and more qualitative work is needed. Linking the two can provide mutual enrichment, which is perhaps even more important. This could also help bridge the gap between life course and biography studies. Recent attempts to add multiple layers of meaning to the somewhat "positivist" empiricist approaches to mobility biographies may be a start.
3. *The social embedding of travel.* Rich research has developed in recent years about personal social networks (including intra-household interactions) and travel. This research has few links as yet to life course and biography perspectives, though the need to understand social networks and travel in a longitudinal sense has clearly been recognised. Future research should also include socialization effects and the social embedding of travel in a wider sense, linking individual behavior over the life course with the behavior of collectives and organizations in policy, the economy or the neighborhood or city of residence, and looking at the role

of social norms over time. The interaction between policy measures and their acceptability and responses on the individual level has been found to change strongly over time, and more research is needed on this topic to support a sustainable transition of travel.

4. *Interactions between life domains, behavioral dimensions, and population groups.* There are also multiple interactions between various life domains, events and developments over the life course. It is not clear yet how multiple events and changes work together to shape mode choice change. This also refers to the sequence in which changes occur, including lead and lagged effects that have clearly been recognized, but rarely studied. Interrelations between various dimensions of travel behavior have been studied in transport research, but hardly in a longitudinal perspective. Previous mobility biographies research has sought to understand direct links between key events and mode choice changes, for instance, but these links may be moderated by changes in activity patterns, destination choice and associated distances, and other variables. Finally, there is a need for dedicated studies of certain population groups that are of special importance to research or policy. For instance, there are few mobility biographies studies on immigrants, the poor, or the elderly.
5. *Develop and test policy approaches.* It is an important task to develop policy approaches that take knowledge from mobility biographies studies into account. Information campaigns, trial tickets and the like that may be linked to life course events such as residential or workplace relocation, the birth of a child, or entry into retirement have proven valuable. On the other hand, policies can make use of socialization effects. Peers and other socialization agents can help target people's travel. "Snowball effects" (effects may be stronger in the long run than in the short run) may increase the effectiveness of concepts. Policies should take path dependencies in people's life courses into account. Early decisions on the locations of residence, education, and workplace can have lifelong consequences for travel behavior, and they can even affect subsequent generations in a family. Policies should also recognize long-term stability in people's travel behavior and recognize that people may adapt their travel slowly and only to a minor extent, even if circumstances in the environment change dramatically.

Acknowledgment

This research was funded by the German Research Foundation (DFG) as part of the project "Veränderungen der Mobilität im Lebenslauf: Die Bedeutung biografischer und erreichbarkeitsbezogener Schlüsselereignisse" (Travel behavior changes over the life course: the role of biographical and accessibility-related key events, 2015–2020).

Introduction

Air transport as the system consists of three main subsystems - airports, airlines, and ATC/ATM (Air Traffic Control / Management). Airports represent the system's ground-based infrastructure consisting of the airside and landside area. Airlines operate the air route networks with flights connecting airports carried out by different aircraft types. The ATC/ATM subsystem embraces the controlled airspace as some kind of the "infrastructure" and the controlling and monitoring facilities and equipment. These all provide capacity to serve demand. For airports, the airline flights, air passengers, and freight/cargo shipments represent demand. For airlines, these are air passengers, and freight/cargo shipments. For the ATC/ATM, the airline flights represent demand. In addition, the air transport system contains the nonphysical components in the format of the operational rules and procedures and information (messages) regulating operations within and among the particular components/subsystems. **Fig. 1** shows the simplified scheme (Janić, 2019). In general, the air passengers and freight/cargo shipments represent the demand for airports and airlines.

The air transport system has been one of the fastest growing sectors of the world's economy. During the period 1991–2007, the air passenger and freight/cargo traffic in terms of Revenue Passenger Kilometers (RPK) and Revenue Ton Kilometer (RTK) (RPK (Revenue Passenger Kilometers) = Number of Transported Passengers · Kilometers Flown; RTK (Revenue Ton Kilometers) = Quantity of Transported Freight · Kilometers Flown) had grown at an average annual rate of 4.5% and 5.7%, respectively. In the year 2007, the volumes had reached about 4.5 trillion RPK and 0.6 trillion RTK. Latter during the period 2008–17, the volumes of RPK and RTK have continued to grow driven by both external and internal driving forces at an average annual rate of 4–5% and 5.5–6.5% and reached about 7.7 and 0.94 trillion, respectively, in the year 2017 (ICAO, 2005/2018). The main external driving forces have been the overall economic growth (gross domestic product (GDP), per capita income (PCI)), globalization of trade, foreign investments, and tourism. The main internal driving forces have included liberalization of the air transport markets driving re-consolidation of the airline industry into two large airline categories (the conventional (legacy) and low cost carrier(s) (LCCs) offering generally lower more attractive airfares. Both types of driving forces have generally resisted to the compromising ones such have been the various large-scale disruptive events (severe weather, September 11, 2001 terrorist attack on the U.S., regional wars—

Figure 1 Main components of the air transport system (Janić, 2019).

Iraq, Afghanistan, Syria), the global economic and political crises (2008), and global epidemic diseases (ACI, 2006; AIRBUS, 2006; Boeing, 2007; ICAO, 2005/2008). In addition, the impacts of the air transport system on the society and environment have been increasing, thus requiring undertaking the measures for its more sustainable development in the forthcoming medium- to long-term period (Janić, 2007, 2009).

The Sub-Systems of Air Transport System

Airports

Infrastructure

The Airport Council International (ACI) has reported that 17,678 commercial airports worldwide have handled air passenger, freight/cargo shipments, and business aircraft (ACI, 2018; <https://store.aci.aero/product/annual-world-airport-traffic-report-2018/>). The number of international airports has been 1282 of which 163 in Africa, 311 in South and North America, 319 in Asia, 498 in Europe, and 51 in Oceania (<https://www.bts.gov/content/number-us-airports/>; https://en.wikipedia.org/wiki/List_of_international_airports_by_country#Number_of_International_Airports).

Each airport consists of the airside and the landside area. The airside area includes runways, taxiways, and apron/gate complex. The runways enable the aircraft landing and taking-offs. The taxiways enable the aircraft movements between the runways and the apron/gate complex. The apron/gate complex provides the space-parking stands for the aircraft ground handling, which includes embarking, and disembarking air passengers, their baggage and freight/cargo shipments after landing, and embarking these after the aircraft refueling and before taking-offs. The landside area consists of the passenger and freight/cargo terminal(s) and the landside access modes and their systems (De Neufville and Odoni, 2013). Fig. 2 shows the simplified scheme of an airport layout.

The passenger and freight/cargo terminals can have different layout and size depending on the volumes of corresponding demand to be served during the specified period of time (hour, day, year) under given conditions. The road- and rail-based landside access modes provide the airport landside accessibility for air passengers, aviation employees, greeters, and others (Janić, 2019). The former mode includes the car and van, and bus systems. The latter mode includes the streetcar/tramway, Light Rail Transit (LRT), subway/metro (short distance), regional/conventional rail and High Speed Rail (HSR) (medium and long distance), Trans Rapid Maglev (TRM) (currently short distance), and most recently the rather futuristic Hyperloop (HL) (long distance) system. These all connect airports with their catchment areas (frequently these are the city centers or Central Business District(s) (CDBs).

Demand/Capacity and Quality of Services

The airport demand consists of the atm (aircraft movements) (1 atm = 1 arrival or 1 departure) in the airport airside area, and the air passengers and freight/cargo shipments in the landside area. The airport capacity is usually defined as the maximum number of units of demand, which can be accommodated in the corresponding area(s) during a given period of time under given conditions (hour, day, year). These conditions are either 'the constant demand for service' ("ultimate" capacity) or the 'maximum average delay' ("practical" or "declared" capacity). The total capacity of airside area depends on the capacity of runway system, taxiways, and apron/gate complex (De Neufville and Odoni, 2013). These capacities should be in balance in order to avoid "bottlenecks" and consequent aircraft/flight delays, additional fuel consumption and related emissions of GHG. An example of the relationship between the

Figure 2 Airport airside and landside area: Case of LGA (La Guardia Airport) (New York, U.S.) (Janić, 2007).

Figure 3 Relationship between the runway systems' "declared" capacity and demand: Case of Dubai International Airport (Dubai, UAE).

runway system "declared" capacity in the form of the "capacity coverage curve" and demand in terms of atms is shown in Fig. 3 (Janić, 2009).

As can be seen, the arrival and departure capacity based on the instrumental flight rules (IFR) are dependent on each other. In some cases, the number of slots exceeds the capacity coverage curve implying that the both arrival and departure aircraft/flight delays can be expected.

The landside area capacity includes that of the passenger and freight/cargo terminals and the landside access modes and their systems. These capacities should also be in balance. They are expressed by the maximum number of served units during the specified period of time under given conditions and similarly as above can be the "ultimate" and "practical." The landside demand appears relevant for operation and planning of the capacity of above-mentioned components of the landside area. Specifically, the annual passenger demand can be used for the medium- to long-term strategic planning of the passenger terminal capacity as shown in Fig. 4 (Janić, 2009).

As can be seen, three solutions for expanding the passenger terminal capacity are proposed to match the prospectively growing demand during the medium- to long-term period.

At the global scale, the quality of services at airports can generally be expressed by their average annual on-time performance, that is, punctuality, defined as the proportion of arriving and departing flights operated within 15 min of their scheduled arrival and departure times (OAG, 2019). In some way, this can generally reflect the quality of services, which airports provide to both airlines

Figure 4 Matching the passenger terminal capacity to demand: Case of Heathrow airport (London, UK) (Janić, 2009).

Figure 5 The total revenues, costs, and profits of the world's airports (Period: 2013) (ICAO, 2015).

and air passengers. Developments so far have indicated that the average annual on-time performance has generally decreased with increasing of the volumes of airport traffic.

Economics

The airport economics relate to their revenues, costs, and profits. The revenues can be roughly categorized as the aeronautical obtained from handling airlines, air passengers, and freight/cargo shipments, and the non-aeronautical obtained from some other commercial (non-operating) activities. Fig. 5 shows these for the airports in the particular world's regions (ICAO, 2015). As can be noticed, the profits were higher than the costs in all regions, which indicate that the airports worldwide were generally profitable.

Airlines

Infrastructure–Air Route Networks and Aircraft Fleet

The commercial airlines and their alliances constitute the airline industry. At present, about 5000 airlines operate in the world. However, only 153 national/flag and 146 LCCs are the International Civil Aviation Organization (ICAO) coded. Of these, almost 290 are the members of International Air Transport Association (IATA). During re-consolidation, that is, while adapting to

Figure 6 Typical spatial configuration of the airline “point-to-point” network(s) and traffic pattern at one of airports. (A) Spatial configuration; (B) Traffic pattern at base airport.

deregulation and liberalization of the air transport markets in combination with facing to growing demand, most airlines have developed different types of air route networks and business models enabling their categorization. The full cost or the network (legacy) airlines and their alliances have developed the large (global) “hub-and-spoke” networks with one or few centrally located “hub” airports. At these “hubs,” the relatively large number of short-medium, and long-haul incoming and outgoing interconnected flights to/from the other “spoke” airports are scheduled during the relatively short period of time (one or couple of hours). As such, they form one or several flight “waves” at the hub airports during the day enabling transfer of passengers between the particular incoming and outgoing flights in the relatively short time windows. Consequently, the shares of transfer passengers at hub airports have substantively increased. The LCCs have developed the “point-to-point” networks consisting of the short- and the medium-haul routes connecting the regional airports and their base airports, which have also been large. They have mainly operated the fleets consisting of single aircraft type. Fig. 6A, B shows the typical spatial configuration and flight/traffic patterns for the “point-to-point” network(s) (Janić, 2009).

Fig. 6A shows that in the “point-to-point” network(s) the airline base airport is connected by most other airports and that these other airports can be mutually connected. Fig. 6B shows that at the airline can schedule the number of flights also above the airport “declared” capacity implicitly incorporating the expected delays in the scheduling. Fig. 7 (A, B) shows the typical spatial configuration and the flight/traffic patterns of the “hub-and-spoke” network (FAA, 2007).

Fig. 7A shows that the spoke airports are connected to the hub and not between themselves. Fig. 7B shows that the flight scheduling at the hub airport in terms of the relative relationship between the numbers of scheduled departure and arrival flights and the airport capacity during the day. As can be seen, the flights form the arrival and departure “waves” in which the demand/capacity ratio has exceeded the value of one thus implying occurrence of the significant queues and delays, just caused by the airline flight scheduling. Consequently, the airlines have already internalized these delays during design of their schedule.

Operating the above-mentioned networks has inherently required deployment of the larger and more diverse aircraft fleet. Consequently, over the past decade and half, the total number of commercial aircraft has increased from 20,356 in the year 2005 to 29,936 in the year 2017, that is, for 47%, that is, it has grown at an average annual rate of 3.9%/year (AIRBUS, 2018; Boeing, 2017;

Figure 7 The typical spatial configuration of the airline “hub-and-spoke” network(s) and traffic pattern at the hub airport: Case of Atlanta Hartsfield International airport (Atlanta, U.S.) (FAA, 2007). (A) Spatial configuration; (B) Traffic pattern at base airport.

Figure 8 Aircraft categories (DVBBSE, 2018).

ICAO, 2005/2018). A common categorization and related main characteristics of aircraft in the airline fleets of the full cost or the network (legacy) airlines and their alliances are given in Table 1 and Fig. 8 (DVBBSE, 2018; <https://contentzone.eurocontrol.int/aircraftperformance/details.aspx?ICAO=E190/&>).

Figure 9 The world scheduled domestic and international air traffic over time (Period: 2005–2017) (ICAO, 2006/2018): (A) Passenger traffic—demand and supply/capacity; (B) Freight/cargo traffic—demand and supply/capacity.

Demand, Capacity, and Quality of Services

During the period 2005–17 the above-mentioned commercial aircraft fleet has supported the growth of the passenger and freight/cargo demand as shown in Fig. 9A, B (ICAO, 2005/2018).

As can be seen, the total passenger and freight/cargo traffic has been growing for about 98% and 81%, respectively, or at an average annual rate of about 5.8% and 5.1%, respectively. The utilization of the available capacity (i.e., load factor) has increased from about 75% to 81% at the passenger and decreased from 68% to 62% at the freight/cargo segment.

The airline quality of services has been expressed, in addition to other measures, by the on-time performance, that is, punctuality, defined again as the proportion of flights arriving and departing within 15 min of their scheduled times. Fig. 10 shows an example for the world's selected airlines. As can be seen, the most punctual have been the mainline airlines, followed by LCCs, and majors (OAG, 2019).

Economics

The airline economics can be considered at different levels such as the individual aircraft and airlines, airline categories—mega, mainline, LCC, regions—continents, and the world airline industry in both aggregate/total and average (per unit of output) term (ASK and PKM). In addition, the particular averages can be expressed over time or depending on the volumes of output during given period. Fig. 11 shows an example of the average revenues and costs of the world's airlines over time (ICAO, 2005/2018).

As can be seen, the average revenues were generally higher than the average costs during the observed period. The exceptions were the years 2008 and 2009 when both were almost equal. After that, they were increasing in parallel until the end of the observed period. This indicates that the airline industry has been overall profitable during the observed period.

Figure 10 The on-time performance, that is, punctuality, of the selected world's airlines (Period: 2018) (OAG, 2019).

Figure 11 The average revenues and costs of the world's airlines (Period: 2005–2017) (ICAO, 2005/2018).

ATC/ATM Subsystem

Infrastructure, Facilities, and Equipment

The ATC/ATM (Air Traffic Control/Management) subsystem is established to provide safe, effective, and efficient air traffic in the controlled airspace. Its main components are the airspace, technical/technological components, and the ATC/ATM staffs.

1. *The controlled airspace* is divided into smaller parts such as: (i) AZ (Airport Zone) embracing the airport airside area; (ii) TMA (Terminal Airspace) containing the approach and departure trajectories towards a single and/or different runways of a given airport(s); (iii) LAA (Low Altitude Area) enabling the aircraft/flight climbing to and descending from the cruising altitude(s); and (iv) high altitude airspace (HAA) where the cruising phase of flights takes place. **Fig. 12** shows such airspace division (Janić, 2009; <http://www.eurocontrol.int/articles/free-route-airspace/>).
2. *The technical/technological components* are CNS/ATM (Communication Navigation Surveillance/Air Traffic Management) systems including communications, navigation, and surveillance systems using digital technologies, and the satellite systems together with various levels of automation, supporting safe, effective, and effective global ATM system. In addition, these are different tools supporting the tactical and strategic control and management of the individual aircraft/flights and the air traffic flows, respectively (<http://www.sesarju.eu/>; <http://www.faa.gov/nextgen/>).
3. *The ATC/ATM staffs system* include the ATC controllers and ultimately the aircraft pilots. The former are responsible for monitoring, controlling, and managing the aircraft/flights in the airspace of their jurisdiction. At the level of ATC/ATM sectors, they are usually organized as teams of two or three persons with precise division of tasks and responsibilities. The pilots participate in the ATC processes by following, in addition to their own, instructions and guidance from the ATC controllers. These mainly relate to maintaining their aircraft on the assigned trajectories and separation from the other aircraft/flights.

Figure 12 Scheme of division of the ATC/ATM system airspace in the vertical plane.

Figure 13 Relationship between the average (unit) cost and the annual number of controlled flight hours in the European and U.S. ATC/ATM system (Period: 2006–2017) (EUROCONTROL, 2019).

Demand, Capacity, and Quality of Services

The ATC/ATM (Air Traffic Control/Management) operates as the sub-system of the ANSP (Air Navigation Service Provider) system, which as being public or private entities provides Air Navigation Services to aircraft/flights during all phases—taking-off, en-route, and landing (ICAO, 2016). These services are as follows: air traffic management (ATM); communication navigation and surveillance (CNS); Meteorological service for air navigation systems (MET); search and rescue (SAR); and AIS/AIM (Aeronautical Information Services/Aeronautical Information Management). At present, 82 ANSP systems in the scope of 166 national Civil Aviation Authority (s) (CAAs) operate in the world. In general, the ATC/ATM subsystems in different regions have possessed different characteristics and performed differently as shown in Table 2 (EUROCONTROL, 2019).

As can be seen, the ANSP is more fragmented in Europe than in U.S. The European area comprises 37 ANSPs with 62 en-route centers and 51 FMPs while the U.S. system controlling for about 10% smaller airspace has comprised only 1 ANSP with 23 en-route centers and 65 TMUs. In addition, the number of controlled airports in Europe has been for about 87% greater than that in U.S. Under such conditions, the U.S. system has handled for about 47% and 47% more IFR and total daily flights, respectively, with about 32% and 43% less ATC controllers and total staff. Despite the higher control time per flight for about 8%, the U.S. system has also performed more effectively regarding the flight arrival punctuality (3%) and the TMA average delays (10%), but worse regarding ATM/TMI flight delays (19%). In addition, Table 3 gives the characteristics of the number of handled flights flight and related delays between airports, that is, in the en-route airspace, of Europe and U.S. (EUROCONTROL, 2019).

As can be seen, during the observed period, an average annual number of 5.1 million IFR flights handled in the European en-route airspace was imposed an average delay of 1.0 min/flight. The proportion of flights delayed more than 15 min was 3.5%/year

Figure 14 Fuel consumption by the world's commercial air transportation over time (Period: 2005–2018) (ICAO, 2005/2018; <https://www.statista.com/statistics/655057/fuel-consumption-of-airlines-worldwide/>): (A) Total fuel consumption versus time; (B) Average fuel consumption versus time.

with an average delay of 29 min/flight. At the same time, an average annual number of 8.6 million IFR flights handled in the U.S. en-route airspace was imposed an average delay of 0.3 min/flight. The proportion of flights delayed more than 15 min was 0.7%/year with an average delay of 38 min/flight. Similarly as in the above-mentioned case of airports, these figures indicate again that the U.S. airspace have handled for about 70% more flights but on the account of about 3 times shorter and 30% longer average delay per flight and per delayed flight, respectively. At the same time the proportion of these (longer than 15 min) delayed flights was for about five times lower in the U.S. than in the European airspace

Economics

The economics of the ATC/ATM sub-system can be considered through its total and average revenues, costs, and profits/losses. In general, the prices of ATC/ATM services bringing the revenues are usually set up to cover the costs for almost 100%. Therefore, it can be said that the costs reflect the revenues. One of the average economics in the given context is the average (unit) ATC/ATM provision cost, usually expressed as the ratio of total system's provision costs and the volumes of output in terms of the flight-hours controlled (The flight-hours controlled have been estimated as the product between the number of controlled flights and time spend for their controlling). This average (unit) cost includes the ATC controllers' employment cost and the supporting cost (non-ATC controllers' employment and the ATC controllers' training and developments, operating, and depreciation/amortization cost). **Fig. 13** shows some cost characteristics of the European and U.S. ATC/ATM system (EUROCONTROL, 2019).

As can be seen, the average (unit) cost per flight-hour controlled was changing during the observed period in both ATC/ATM systems. It was the highest in the year 2008/2009 when the number of flight-hours was decreased due to decreasing of the number of flights caused by the global economic/financial crisis. In addition, this cost was for about 44% higher at the European than U.S. ATC/ATM system during the observed period.

Figure 15 The land used by the world's spacious airports (<https://www.worldatlas.com/articles/the-largest-airports-in-the-united-states.html/>).

Sustainability of Air Transport System

General

The sustainability of air transport system generally relates to its impacts and effects on the society and the environment and their balance in the medium to length period. Its operations create the environmental impacts such as energy/fuel consumption and related emissions of green house gases (GHG) and land use. The social impacts are direct congestion and delays, noise, and safety, that is, traffic incidents/accidents. If internalized, that is, charged, these impacts represent area considered as externalities. The system's effects are contribution to the local, national, and international employment and GDP and consequently the overall social-economic welfare. Both externalities and GDP-contributions can also be considered in the scope of the system's economic performance (Janić, 2007; https://www.icao.int/sustainability/Airport_Economics/State%20of%20Airport%20Economics.pdf/).

Fuel Consumption and Emissions of GHG

The commercial turbojet aircraft mainly consume Jet A fuel or kerosene as a derivative of crude oil. Their fuel consumption over the past decade and half at the global (the world's) scale is shown in Fig. 14 A, B (ICAO, 2005/2018; <https://www.statista.com/statistics/655057/fuel-consumption-of-airlines-worldwide/>).

Fig. 14A shows that after some stagnation at the beginning (2005–07), the total fuel consumption has continuously increased at an average annual rate of 4.7% during the remaining period 2008–17. Fig. 14B shows that the average fuel consumption (g/RPK) has decreased for of about 30%, that is, at an average annual rate of 2.5% during the observed period. Burning Jet A fuel produces GHG of which the most voluminous are CO₂ (Carbon Dioxide) and H₂O (water vapor) emitted at the rate of 3.162 kgCO₂/kg and 1.23 kgH₂O/kg (ICAO, 2014). By multiplying these rates by the above-mentioned fuel quantities, the corresponding total and average emitted quantities of GHG can be estimated. For example, Fig. 13A shows that the total fuel consumption in the year 2016 was 272.552 million tons. This produced 272.552 (3.162 + 1.23) ≈ 1197.048 million tons of CO_{2e} (Carbon Dioxide equivalents). The average external cost of emitted CO_{2e} has estimated to be 212 USD/ton (NAE, 2004; IWG, 2016). In the given case this makes the total costs of emissions of CO_{2e} of 253774.257 million USD or 0.0061 USD/ASK and 0.0075 USD/RPK in the year 2016 (USD - U.S. dollar).

Land Use

Land is used for the airport airside and landside area. Fig. 15 shows the land used by 15 world's most spacious airports (<https://www.worldatlas.com/articles/the-world-s-10-largest-airports-by-size.html/>).

As can be seen, King Fahd (Saudi Arabia) is the most and Frankfurt (Germany) the least spacious airport. In addition, 7 U.S. are among 15 world's most spacious airports. The above-mentioned economics of airports implicitly also reflects economies of their land use. There may be also diseconomies of land use in some cases materialized through changing (diminishing) the value of nearby properties due the impacts such as the aircraft noise, emissions of GHG, and risks of air traffic incidents/accidents potentially damaging properties and threatening lives of the nearby/local population (Janić, 2016).

Figure 16 Air traffic accident rate over time (Period: 2005–2018) (<https://www.icao.int/safety/iStars/Pages/Accident-Statistics.aspx/>).

Congestion and Delays

If internalized, the average unit cost of flight delays including the airline operating costs and the cost of passenger time have estimated to be about 81€/min in Europe and 38 min in the U.S. According to Table 3, the cost of en-route delays per delayed flight would be 29 min · 81€/min = 2349 € in Europe and 38 min · 75 USD/min = 2850 USD in the U.S. during the observed period (WU, 2011; <http://airlines.org/dataset/per-minute-cost-of-delays-to-u-s-airlines/>). These costs can also be considered in the scope of the system's economics.

Noise

The relevant aircraft noise is generated near airports by the aircraft taking-offs and landings. In addition to the absolute levels of noise by particular aircraft types, the number of population exposed to the certain levels of noise can be an indicator of the system sustainability respecting to noise impact. In general, regarding the aircraft noise, the US FAA (Federal Aviation Administration) has established the level of day-night level (DNL) of 65 dBA as the threshold or “significant” level. The EEA (European Environmental Agency) has established the threshold level of L_{den} (Level day evening night) of 55 dBA (dBA—decibel). Above these levels, the aircraft noise is considered incompatible with the residential areas. Table 4 gives the population exposed to the aircraft noise around the U.S. airports during the given period (US DOT/FAA, 2015).

As can be seen, despite increasing the number of population, its absolute number and the corresponding proportions exposed to the above-mentioned threshold noise level were decreasing over time, thus indicating the substantive achievements in dealing with the noise burden around the country's airports. This was carried out by the stricter aircraft certification, advanced operational procedures (noise abatement procedures), and improved land use compatibility embracing residential, public, commercial, manufacturing, production, and recreational areas. The excessive noise has been charged at many airports worldwide. These charges have been frequently included into the airport landing fees based on the aircraft noise categories mainly influenced by their size, that is, MTOW (Maximum Take-Off Weight).

Air Traffic Incidents/Accidents (Safety)

The air transport system, like other transport systems, has not been free from the air traffic incidents/accidents. In particular the accidents have resulted in damages of property (aircraft involved), losses of lives and injuries of air passengers and crew on board, destroying freight/cargo shipments, and losses of the third parties involved. Therefore, in the narrower sense (not including the eventual environmental damages) these can be considered as the physical impacts on the society and related costs/externalities rather than on the environment. According the current practice the air accidents have been investigated in order to identify their causes and undertake the appropriate actions aiming at preventing their occurrence due to the already known (investigated) causes. This has resulted in continuous reduction of the number of these accidents despite increasing of the number flights/departures over time, as shown in Fig. 16 (<https://www.icao.int/safety/iStars/Pages/Accident-Statistics.aspx/>).

During the last 10 years (2008–18), the rate of air accidents has decreased for about 63%, that is, from 4.70 to 1.75 events per million annual departures. At least from the statistical point of view this indicates that over time the system has become increasingly safer. Some estimates indicated that the costs of air accidents have been substantive. As an illustration, they were 223 million €/year or 500 €/RPK in the year 2008 in the EU-27 Member States. This amounted 3.33% under low and 0.875% under high scenario of the total external costs.

Contribution to the Social-Economic Welfare

Contribution of the air transport system to the social-economic welfare consists of its employment and created GDP. In the year 2014, the total number of employees was 62.7 million and the created GDP 2.7 trillion USD worldwide. This gives about 43062 GDP USD/employee-year. The highest employment was in Asia-Pacific and the lowest in Middle East region. That in Europe was higher than in North America. At the same time, the highest GDP was created in Europe, followed by that in North America and Asia Pacific region. The lowest GDP was created in Middle East. The highest GDP/employee was in North America followed by Europe and the lowest in Africa region. Some estimates indicate that the total employees by in the year 2034 the air transport system worldwide will increase to about 99 million people and generated GDP to 5.9 trillion USD (ATAG, 2018).

Conclusions

The air transport system worldwide and in particular regions/continents has been growing fast during the past two decades in terms of both air passenger and freight/cargo transportation. The system's external and external driving forces have driven growth of demand served by the supply of adequate system capacity. The former forces have generally included growth of population and GDP, and globalization of international businesses, trade, and tourism. The latter fares have embraced liberalization/deregulation of the air transport markets, consolidation of the airline industry including strengthening of LCCs, and generally decreasing airfares. Consequently, the airlines have increased size and diversity of their aircraft fleets, the airports and ATC/ATM operators have been faced with the shortage of capacity, requesting substantive investments in order to maintain quality and safety of their services at the required level.

The air transport system will continue to grow driven by both already known external and internal prospectively strengthening driving forces. This will require provision of more capacity at all three subsystems—airports, airlines, and ATC/ATM—in combination with further improvements of the efficiency, effectiveness, and safety of operations and related transport services. In parallel, the system will be faced with increasing global and local requirements to be more sustainable, that is, “greener”, regarding all above-mentioned impacts on the environment and society. On one hand, this is expected to be achieved by the technical/technological, procedural, and operational innovations. On the other, these previous would be combined with the policy and economic measures including imposition of the procedural and operational constraints and charging particular impacts as externalities.

Introduction

The invention of the airplane in 1903 by the brothers Wilbur and Orville Wright fulfilled a dream of centuries, giving humanity a practical means of overcoming the vicissitudes of travel across turbulent seas and daunting landscapes. By inventing a means of locomotion that was free of the retarding constraints of geography, moving easily through the air in any direction, the brothers effectively gave to the world three-dimensional mobility. They did so by reviewing and expanding upon the work of European and American researchers such as Sir George Cayley, Otto Lilienthal, and Octave Chanute, adding their own creative insights (particularly in the field of aircraft stability and control), and carefully integrating the four great fields of aeronautical science— aerodynamics, structures, propulsion, and controls—to make the first successful airplane, defined as one capable of powered, sustained, and controlled flight (Gibbs-Smith, 1960; Hallion, 2003; Jakab, 1990).

Less than a century previously, the invention of the steam engine had furnished a motive means of power that revolutionized two-dimensional surface travel. By the early 20th Century, steam-powered vessels were traversing the world's oceans at up to 30 kts (approximately 35 mi/h, or 56 km/h), and steam-powered locomotives were reaching speeds of 60 mi/h (69 km/h) on rail lines that crossed international frontiers, linking the world's major cities. But, being heavy in relation to its power output, the steam engine was not suitable as a practical propulsion system for aircraft. Fortunately, the petroleum revolution, coupled with the advent of the internal combustion engine, enabled the construction of lightweight piston engines capable of furnishing power for flight. The invention of the airplane propeller—essentially a rotating wing generating a horizontal lift vector that pulled the airplane through the air—completed the foundational base for flight propulsion enabling the Wrights to develop a successful aircraft (Hobbs, 1971; Kinney, 2017).

As well as enabling the practical airplane, the petroleum-fuelled engine made possible the practical airship. In contrast to the heavier-than-air airplane, dependent upon aerodynamics—the lifting force of air circulating around its wings (and thus requiring a certain minimum speed, varying from design to design)—to remain aloft, the lighter-than-air airship exploited aerostatics—being buoyed by flammable hydrogen or (in the fortuitous case of America) inflammable helium lifting gases.

This chapter is organized as follows: the first section examines the airship and its failure as a viable air transport vehicle; the second traces the evolution of the airplane and air commerce to the end of the 1930s; the third section discusses the influence and the reshaping of civil aviation after the Second World War; the fourth examines the transition into the jet age and the beginning of mass air travel; the fifth section traces the ending of American air transport hegemony, and the last section offers a summary and conclusion stressing the rise of a “green” consciousness and desire for better environmental stewardship by the global aerospace community.

The Dirigible Airship: A False Path

The prospect of large passenger dirigibles—large rigidly-framed airships containing internal gas cells and multiple engines, most popularly typified by the German Zeppelin airships produced by the firm of their eponymous creator, Ferdinand Graf von Zeppelin—attracted great attention in the first three decades of powered flight. But an international series of dirigible disasters involving American, British, French, and German airships brought the era of the passenger dirigible to a close, most notably the highly publicized loss of the German Zeppelin airship Hindenburg in a landing accident at Lakehurst, New Jersey, in 1937. Although hydrogen conflagrations such as the ill-fated Hindenburg's attracted the greatest attention, the airship's major problem was structural weakness, for many of these large gravity-defying vessels, whether hydrogen-or-helium filled, measured over 750 ft (228.6 m) in length (and sometimes well more), and they were prone to breaking up in storms or from routine air turbulence that would not harm an aircraft. Indeed, considering their fatalities in relation to total flights, dirigible airships hold the dubious distinction of being the most lethal form of mass transportation ever developed. As well, they required immense logistical support, which made them as well the most expensive means of long-range personal travel (Brooks, 1975; Robinson, 1973).

Nevertheless, despite their problems, the credit for the first commercial air transport service goes not to the airplane, but to the airship: in 1909 von Zeppelin, in conjunction with the Hamburg-Amerika shipping line, formed DELAG, the German airship corporation, eventually operating six airships on a sporadic service that, before the First World War, carried 19,100 passengers and flew 65,000 mi (104,650 km) in the course of 881 flights (Davies, 1967).

The Airplane and Early Air Commerce

Experiments in using aircraft for commercial operations took place before the First World War, pioneering carrying cargo, mail, and passengers, subsequently the three major purposes of air transport. On November 7, 2010, Wright pilot Philip Parmelee completed the world's first air freight flight, delivering 100 lb of fine silk to the Morehouse-Martens Company for a cost of \$5,000—equivalent to \$128,000 in 2019—in a flight from Dayton to Columbus, Ohio. On February 18, 1911, Henri Piquet delivered the first air mail parcel on a flight between Allahabad to Naini in the then United Provinces of Agra and Oudh (now the Indian state of Uttar Pradesh). On January 1, 1914, aviator Tony Jannus began the world's first scheduled airplane passenger service on a short flying boat service from St. Petersburg to Tampa, Florida, carrying 1,204 passengers over three months before the service ended, having failed to turn a profit (Davies, 1967; Lane, 1986; Reilly, 1997).

The widespread use of aircraft in the First World War—including using military aircraft to routinely transport dispatches and orders—accelerated the emergence of scheduled air transport immediately after the Armistice (Hallion, 2014, 2018). Even before the end of the war, in 1918, the US Army and the US Post Office had collaborated on establishing the world's first scheduled air postal service, which was privatized after the war. In 1919 three flights crossed the North Atlantic, highlighting the extraordinary technical development of aviation in the decade after 1910: the first by an American flying boat, the second by a converted British bomber, and the third by a British dirigible (Heppenheimer, 1995; Leary, 1985; Linden, 2002; Loftin, 1985).

Though it had invented the airplane, America lagged behind Europe both in the scientific study of flight and in the development of cutting-edge aerodynamic and structural advances. Only by exploitation and elaboration upon German-rooted scientific aerodynamics and structural practices—exemplified by the cantilever (internally braced) thick-wing monoplane and all-metal construction—did the United States catch up, and then surpass, the European nations. By 1930 streamlined “air express” designs by John K. Northrop (working first for Lockheed, then for United Aircraft, and finally on his own) led the world in speed and performance, triggering foreign emulation. In 1933 Boeing and Douglas introduced streamlined twin-engine transports that, attaining flight speeds over 200 mph, revolutionized global air transport design standards. The most advanced of these was the Douglas DC-3, which carried 21 passengers at a maximum speed of 230 mi/h over a range of 2,125 miles, at an operating cost that was just a third that of the earlier 17-passenger Ford 5-AT-C Tri-Motor. The DC-3 became an immediate international success: it was license-produced abroad, and influenced the design of subsequent Russian, Japanese, German, French, and Italian air transport aircraft (Brooks, 1961; Hallion, 2009; Miller and Sawers, 1970).

Over the interwar years, aviation technology advanced rapidly, exemplified by the transformation of the airplane from a wood-and-fabric externally braced biplane to an all-metal monoplane with internally-braced cantilever wings and a streamlined monocoque (shell) fuselage. Accompanying this configuration change were other developments that enhanced aircraft performance including the introduction of retractable landing gears, controllable-pitch propellers, the air-cooled radial engine and streamlined engine cowling, and lift-enhancing wing flaps and leading-edge airflow-controlling wing slots and deployable wing slats. The first application of all-metal and streamlined cantilever design was by German designer-entrepreneurs, notably Hugo Junkers, Adolf Rohrbach, and Claudius Dornier. The appearance of high-performance civil aircraft immediately after the war—beginning with the Junkers F 13 of 1919—reflected the inherently “dual-use” (military-civil) nature of the aeronautics infrastructure underpinning aircraft design (Brooks, 1961; Hallion, 2017; Hirschel et al., 2004; Jarrett, 1997; Loftin, 1985; Miller and Sawers, 1970). Accompanying these developments in airframe design and propulsion were equally significant developments in radio communications, radio navigation and radio beacons, blind-flying instrumentation, radar, instrument landing systems, aviation weather prediction, and airways development and regulation (Volti, 2015; Whitnah, 1966).

Though prewar European air commerce advocates had formed an International Commission for Air Navigation (ICAN) and held periodic meetings, the practical development of an international airline structure only began after the First World War with the formation of the German airline Deutsche Luft Reederei, offering a service between Berlin, Leipzig, and Weimar, using converted military airplanes. Other lines quickly followed across Europe, particularly France, Britain, and Holland, and by the mid-1930s these had coalesced or merged into the great foundational lines of global air transport, Imperial Airways (predecessor to British Overseas Airways Corporation and the modern British Airways), Air France, Lufthansa, Swissair, and KLM (Bluffield, 2009; Davies, 1967; Heppenheimer, 1995; Trimble, 1995).

Having been slower than Europe in supporting aeronautics via government oversight and regulation, America was slower than Europe as well in developing an airline structure, which it did only after passage of key legislation including the Kelly Act of 1925, and the Air Commerce Act of 1926, the latter act marking the birth of what would eventually become the American Federal Aviation Administration (FAA) (Whitnah, 1966). By the mid-1930s, major American airlines such as United, American, and Transcontinental and Western Air (predecessor of TWA), buttressed by smaller regional lines, offered wide-ranging domestic service while Pan American Airways, America's “Chosen Instrument” for international air commerce, offered routine service throughout the Americas and reaching across the Pacific to China (Daley, 1980; Mayo et al., 2009; Van Vleck, 2013). The latter reflected the geography of the United States, separated from its Asian and European nations by vast oceans, which stimulated the development of

what were, in their time, the world's most technically advanced long-range flying boats, designed by the Consolidated, Sikorsky, Martin, and Boeing companies (Smith, 1983). By the end of 1936, Juan Terry Trippe, founder of Pan American Airways, had pioneered air mail and passenger services through the Americas with Consolidated Model 16 and Sikorsky S-38 and S-40 flying boats and across the Pacific to China by island-hopping Martin M-130s and Sikorsky S-42s. In 1939 he extended Pan American's operations to Great Britain and France with the Boeing 314 (Daley, 1980; Davies, 1967; Leary, 1992).

Britain's Imperial Airways and France's Aéropostale and later Air France extensively employed their own flying boats, though typically of lesser range since the Eurasian landmass and the comparatively small area of the Mediterranean permitted shorter hops by mixed-land-and-flying boat services reaching as far as Australia. Holland's KLM made extensive use of new Douglas DC-2 and DC-3 airliners to reach throughout Europe and as far as the then Netherlands East Indies (now Indonesia). Italy developed a comprehensive network through Europe, the Mediterranean and into Africa. The most extensive European airline, however, was Germany's Luft-Hansa (later Lufthansa), which operated landplanes throughout Europe, Russia, and Asia, and an air-mail flying boat service using a mix of packet boats and catapult seaplanes. To Germany goes credit both for the first nonstop East-to-West crossing of the Atlantic, and the first Atlantic-spanning four-engine landplane, the Fw-200 of 1938, anticipating the normative propeller-driven oceanic air transports of the 1940s–1950s. The Soviet Union made extensive use of air transport via a variety of services and partnerships flying a mix of foreign and domestic designs. Japan developed an airline structure through its client states and islands, and its transport design, like that of the Soviet Union, reflected largely German and American landplane and flying boat influence (Bluffield, 2009, 2014; Davies, 1967; Dierikx, 2008; Hirschel et al., 2004).

The Second World War and Reshaping Postwar Civil Aviation

The Second World War (1939–1945) was a war in which air mobility proved of crucial importance, highlighting both the strengths and weaknesses of prewar civil aviation development. In May 1940, for example, Britain's paucity of air transport aircraft necessitated a small-boat seaborne extraction of its soldiers from the beaches at Dunkirk. Similarly, having deemphasized transport development in favor of combat aircraft in the later 1930s, Germany was unable to meaningfully supply its entrapped forces at Stalingrad in 1942–1943. In contrast, the United States became the great supplier of air mobility (and aviation in general) to the Allied cause, with a wide range of airliners-turned-transport, including the ubiquitous DC-3, the newer Douglas DC-4 four-engine transoceanic landplane, the Lockheed 049 Constellation, and other types. By 1945 having mobilized American airline personnel, the US was running an average of 175 transport flights per week across the Atlantic, and, after the end of the war, it launched its first nonstop landplane service across the Atlantic in October 1945 (Bilstein, 2001; Smith, 1969).

In 1943, not wishing to find itself dependent upon American airliners in the postwar era, the British government formed a special wartime committee, the Brabazon Committee, to direct the future fortunes of British civil aviation. While it identified a number of potential new designs, and influentially advocated for both pure turbojet and turbo-propeller future airliners, it could not overcome at war's end both the vast numbers of available surplus American aircraft and newer designs, and crippling decisions by Britain's postwar Labour government (Engel, 2007; Fedden, 1957; Hayward, 1989). By 1951 80% of the world's airliners were American built, and, of these, nearly 60% were from a single firm, Douglas (Brooks, 1961; Miller and Sawers, 1970). Until the advent of Airbus in the 1970s, postwar global air transport was thus dominated by designs from the Douglas, Boeing, and, to a lesser extent, Lockheed companies (Bilstein, 2001; Brooks, 1961; Dienel and Lyth, 1998; Staniland, 2003). The Soviet Union went its own way, its state airline, Aeroflot, making use of war-surplus license-built Lisunov DC-3 derivatives, and subsequent indigenous designs by Antonov, Ilyushin, and Tupolev (Stroud, 1968).

Before war's end, in late 1944, the United States sponsored an international meeting, the Chicago Convention on International Civil Aviation. On 7 December 1944, members formed a Provisional International Civil Aviation Organization (PICAO) to replace the ICAN. The PICAO took effect in June 1945, after the collapse of Nazi Germany, but two months prior to the end of the war in the Pacific. In March 1947 following ratification by 26 nations, it became the ICAO, subsequently being placed under the aegis of the United Nations that October. Formation of the nation-centric ICAO was accompanied by formation of the International Air Transport Association (IATA), an association of 57 of the world's leading airlines, successfully urged by Pan Am's Trippe as a successor to the earlier International Air Traffic Association, formed in 1919; its membership has subsequently grown to 290 airlines. Both worked to steer the fortunes of post-war air transport from the era of the propeller-driven airplane into the era of the jet airliner (Heppenheimer, 1995).

The end of the Second World War marked the end of the great era of commercial flying boats and the onset of the so-called "jet age." By war's end, the global network of airfields rendered the flying boat airliner—compromised by the necessity of having a heavy and aerodynamically inefficient boat hull, together with drag-producing stabilizing sponsons or wingtip floats—obsolete for all but exceptional use. The gas turbine "jet" engine promised routine flight speeds above 500 mi/h (800 km/h) for pure-jet aircraft and cruising speeds well above 300 mi/h (500 km/h) for turbo-propeller ("turboprop") designs. Developed in the late 1930s by German and British pioneers, and transplanted to the United States in 1941, the jet engine was quickly applied to military aircraft, then to civil aircraft. The first civil gas turbine airliner was Britain's Vickers Viscount of 1948, a Brabazon Committee design, which achieved modest international success. Likewise, the first pure-jet airliner was the troubled British de Havilland D.H. 106 Comet of 1949, followed within a fortnight by an experimental Canadian airliner, the Avro of Canada C.102 Jetliner, which introduced the term "jetliner" and was, altogether, an extremely promising design that was unwisely cancelled. America only developed a jet airliner in 1954, with the Boeing 367-80, progenitor of the 707 family; France and Russia followed a year later with the Sud Caravelle and the

Tupolev Tu 104. But these later designs benefited from advances in high-speed aerodynamics, most distinctively the moderately swept-back wing, which enabled these second-generation jet airliners to fly at speeds over 600 mi/h (1000 km/h) (Bright, 1978; Green and Cross, 1957; Stroud, 1994).

The Transition from Piston to Gas Turbine Airliners

Perhaps surprisingly, the introduction of jet airliners did not receive immediate endorsement by airline operators. In part this was due to the catastrophic failure of early Comets due to fatigue-induced explosive decompression at high altitudes, but as well it reflected the inherently high fuel consumption of the pure turbojet that drove up operating costs (overcome by the advent of the so-called “bypass” fanjet engine), and the vast availability of long-range propeller-driven airplanes such as the Douglas DC-4/DC-6/DC-7, the Lockheed 049/749/1049/1649, and the Boeing 377 Stratocruiser operated by airlines including Pan Am, TWA, United, American, Delta, Northwest, BOAC, Lufthansa, Sabena, KLM, Air France, Alitalia, Swissair, and JAL. In the wake of the Comet’s accidents, the Soviet Union was, for over a year, the only country with a civil jetliner in service, the Tu 104, a passenger derivative of the Tupolev Tu 16 bomber (Jarrett, 2000; Stroud, 1968, 1994).

American airlines did not place their first civil jetliners—the Boeing 707 and Douglas DC-8—in service until the end of 1957. But over the year after it did so, tellingly, more than a million passengers flew across the North Atlantic, surpassing for the first time the number of passengers carried across the Atlantic by ship. More fuel-efficient (and hence longer-range) turbofan-powered derivatives of the first 707s and DC-8s continued American market dominance of intercontinental aviation, despite introduction of potential rivals such as the British Vickers VC-10, the Soviet Tupolev Tu 114 (a large sweptwing turboprop airliner derived from the Tu 20 bomber), and the Ilyushin Il 62, the latter closely resembling the VC-10. While the Il 62—which was, essentially, an aerodynamic copy of the Vickers VC-10—was produced in sizable numbers for Soviet and Warsaw Pact airlines, it did not achieve Western market penetration. For its part, the VC-10, though a technically excellent design, likewise proved unable to break the Boeing-Douglas stranglehold on global airline jetliner markets. As jets gradually dominated on domestic and international routes, older legacy propeller-driven designs were employed increasingly for air freight and cargo operations (Brooks, 1961; Dienel and Lyth, 1998; Jarrett, 2000; Miller and Sawers, 1970; Smith, 1969; Stroud, 1994).

From the late 1950s onwards, airlines introduced increasing numbers of short-to-medium range turboprop airliners such as the Fokker F-27, Nihon YS-11, Nord 262, Vickers Viscount, Lockheed L-188 Electra, and, slightly later, a family of Canadian short-take-off-and-landing (STOL) intercity and regional airliners, the de Havilland of Canada DHC-6/DHC-7/DHC-8. Following the example set by France’s Caravelle and the Soviet Union’s Tu-104, over the early 1960s and into the 1970s airlines introduced medium-range jetliners (such as the Hawker Siddeley Trident, British Aircraft Corporation 1-11, Boeing 727, Douglas DC-9, Tupolev Tu 124/134, and Fokker F-28). The end of the decade witnessed the first flights of supersonic transports (SSTs), the Tupolev Tu 144 (December 1968) and the Franco-British Aerospatiale-BAC Concorde (March 1969), and, sandwiched between them, the first widebody “jumbo” jetliner, the Boeing 747 (February 1969) (Jarrett, 2000; Stroud, 1994).

While SSTs proved a false start—the fuel-burn required to overcome high aerodynamic drag rise while passing through the speed of sound made them unattractive to profit-minded airlines, and America abandoned plans to develop its own SST to match the Concorde and Tu 144 largely over environmental concerns—they did enter service with Aeroflot, Air France, and British Airways, largely as symbols of national prestige and technical capability. Capable of cruising at over Mach 2—twice the speed of sound—the Franco-British Concorde remained in service until 2003, though the Tu 144 was quickly withdrawn from service and remained largely in experimental status (Horwitch, 1982).

The emergence of the Boeing 747, however, was a milestone event in commercial aviation, not merely because of its size, but because it signaled the birth of mass commercial air transportation. Overcoming initial sluggish sales and underutilization, the Boeing 747 benefited from airline deregulation to become the greatest long-range people-mover in history, moving hundreds of millions of passengers around the globe over a half-century of continuous flight operations (Sutter and Spenser, 2006). Made possible by the advent of the high bypass ratio turbofan engine, it led to an era of mass air transport that witnessed the development of numerous other wide-body two-three-and four-engine designs by American, European, and Soviet (later Russian Federation) companies and design bureaus, and tremendous expansion of the global airline market, leading to the emergence of a multinational, closely intertwined, and highly regulated air traffic infrastructure. The advent of other technical advances, particularly electronic flight and engine controls; advanced autopilots and stability augmentation; composite structures; computational fluid dynamics; computer-aided design and manufacture; global satellite-based communications, weather, and navigation; and ever-more-powerful, fuel-efficient, and environmentally cleaner fanjet engines; all combined to make air transportation more efficient, safer, and environmentally friendly than other traditional forms of mass transportation such as trains, buses, automobiles, and ships. By the 100th anniversary of the Wrights’ first flights at Kitty Hawk, the world’s airlines had flown nearly 36 billion passengers in roughly eight decades of commercial service (Clark, 2017; Dempsey and Gesell, 1997; Dierikx, 2008; Hayward, 1994; Hirst, 2008; Newhouse, 1982).

Leveling the International Airliner Playing Field

Beginning gradually in the 1970s, the American lock on international civil aeronautics was broken with the advent of foreign-manufactured regional airliners. While aircraft such as the British Viscount and BAC 1-11, and French Caravelle had achieved some

American market penetration, the widespread introduction and acceptance of designs such as the Brazilian Embraer family of turboprop and turbofan regional airliners, the de Havilland of Canada STOL family, the Fokker F-27 and later F-28 and F-100, and the subsequent French ATR-42/ATR-72, British BAe 146, Swedish SAAB 2000, and Canadair (later Bombardier) Regional Jet family signaled that European and other manufacturers could successfully design and market aircraft meeting stringent FAA safety standards and acceptable to American carriers. By 2019 American regional jet fleets were almost entirely equipped with Brazilian and Canadian designs, with a sprinkling of Swedish, French, and British ones as well.

More significant still, the market dominance Boeing and Douglas had over nearly four decades over intercontinental aviation disappeared with the rise of the Airbus in the 1970s. An international consortium established in late 1970 among German, French, British, Spanish, Dutch, and Belgian partners, Airbus flew its first jetliner, the A300B, in October 1972. The A300 gave rise to multiple successors offering great commonality among the types, and which enjoyed widespread success in penetrating the US domestic and international jetliner market beginning with two notable sales orders, the first from Eastern Airlines in 1978 and the second from Pan American in 1984. The advent of Airbus put increasing pressure upon Boeing and McDonnell-Douglas, and contributed to the latter's decline (it eventually merged with Boeing in 1997). Since the Boeing McDonnell-Douglas merger, international air transport fleets have been effectively split between Boeing and Airbus. Arguably, while each rival has stimulated the best from the other, as well, each has at critical points retained or extended its market share based on the other's failures. Examples include Boeing's misstep in attempting to develop a radical canard "sonic cruiser" in 2001, Airbus's misstep in developing the A380 super jumbo, which failed to achieved widespread success, and, most recently, Boeing's troubled 737-Max, which, after two accidents, was grounded worldwide, a grounding still in effect at the time of this writing (Lynn, 1997; Stroud, 1994).

Summary and Conclusions

The growing environmental movement and concerns over good stewardship have led to greatly increased emphasis on reducing even further the fuel burn and emissions of turbofan-and-turboprop-powered aircraft, as well as great interest in finding other means of power generation and motive propulsion via electrical technology. This interest has led as well to revised aerodynamic configurations possibly featuring blended wing-bodies, very broad high-aspect-ratio wings, greater use of lighter composite structures, and advanced flight control systems enabling reductions in the drag-producing size of stabilizing surfaces such as horizontal and vertical tails. In this regard, the earlier derivation of so-called "supercritical" wing and wingtip winglet design has already worked to increase attainable ranges and payload capacity for a given amount of fuel and energy expenditure.

A century after the onset of commercial aviation after the First World War, air transportation has become ubiquitous; by 2010 airplanes carried approximately two billion passengers annually, and 40% of international tourists, with a global economic impact of nearly \$4 trillion USD. If it has lost some of the glamour and exclusivity associated with it during the early jet age, it has become much more commonplace as a means of furnishing humans at every level of society rapid, global-ranging transport, and in bringing together peoples and cultures for the betterment of our shared future. Note to readers: This text was prepared prior to the COVID-19 global pandemic which erupted in early 2020. The effects of the pandemic on air transport have been profound, resulting in numerous aircraft retirements, groundings, and air traffic disruption. The subsequent future of air transport will be critically dependent on how the COVID-19 crisis is addressed by the world's medical and political leadership.

Introduction

Air transport is a central component of the functioning of contemporary society and the modern world order. It is also inherently geographical as it concerns the safe, rapid, and routine, but also the spatially uneven, socially inequitable and environmentally degrading, movement of people and goods between prescribed geographic locations. The development and widespread utilization of air transport for commercial civilian purposes during the 20th century has changed not only the patterns and processes of long distance (and often international and intercontinental) transport and human migration but also created new ways of becoming and being aeromobile. In the process, commercial air transport has been responsible for changing the face of the earth as terrain is flattened, mountains sculpted, coastal areas reclaimed, and rivers diverted to satisfy the exacting technical requirements and safety standards associated with new runways and ever larger airports. Air transport's influence has also extended into global culture and the lexicon of everyday conversation with talk of "autopilots", "flying high" and "taking off" becoming metaphors for the challenges and successes of modern life.

As the second decade of the 21st century commences, air transport has grown to the point where in excess of 1300 airlines, operating almost 32,000 aircraft, fly over 4.7 billion passengers each year between 3800 airports worldwide. At the busiest global hubs, an aircraft lands or departs every 45 s while the A380, the largest commercial aircraft currently in service, is certified to carry up to 853 passengers. Driving society's apparently insatiable demand for aeromobility is the need to move goods from their point of manufacture to their point of consumption and people from where they are to where they want to be in the safest, quickest, and most cost-effective manner possible. Air travel is a derived demand designed to overcome (as far as possible) the limitations of gravity and terrestrial geography, and thus it is subject to fluctuations in the health of the global economy, as well as emerging transborder security threats, variations in oil prices and the vagaries of international political relations. In the following sections, we document what we have termed the "historical" geographies of air transport, which roughly correspond to the period between the mid-18th and late 20th centuries, and the "contemporary" geographies of air transport which commenced at the turn of the millennium.

The Historical Geographies of Air Transport

Although it has proved impossible to accurately determine where the chronological development of air transport begins, historical evidence indicates that humans have been trying to "conquer" the air since before the middle of the third century B.C. when Aristotle began to seriously consider the practicalities of flight. Yet the idea of, and desire for, flight has influenced human civilization since ancient times, with many cultures and religions containing accounts of mythical creatures or deities carrying people up into the heavens. Although gravity and human physiology proved an insurmountable barrier for centuries, by the mid-18th centuries, advances in scientific understanding and experimental method led first to the development of aerostatic flight involving tethered balloons filled with hot air and, later, aeromobile flight in free flying hot balloons. Developments with fixed wing gliders followed throughout the 19th century. But while gliders permitted some element of directional control, they obliged aviators to land at a point lower in elevation from that which they departed, and the lack of propulsion ensured that the effective range of the machines was limited.

By the turn of the 20th century, aeronautical efforts were increasingly being focused on creating an engine that was sufficiently powerful and reliable yet simultaneously light enough to be installed on an aircraft. According to most conventional histories of flight, the world's first successful heavier-than-air powered human flight occurred on the morning of 17th December 1903 on the sand dunes of Kitty Hawk, North Carolina when Orville Wright accelerated his aircraft along the ground. Although the flight was short (it could have been accommodated within the economy class section of a B747), it marked the first time that a human had taken off, sustained controlled level flight and landed at a point that was at least equal in elevation to the point of departure. Crucially, the physical location of the flight was deliberately selected on account of its geography-the dunes were located away from human settlement, the lack of vegetation ensured the local flora posed no hazard, the sand provided a supportive surface, and the constant wind would blow over the wings of the aircraft to generate lift. Despite photographic evidence of the flight, many national

politicians and scientists remained sceptical and as late as 1908 the British Government maintained that flight by a heavier than air machine was impossible.

Between the Wright Brothers' first successful flights of December 1903 and the outbreak of the First World War in 1914, aviation developed without any real expertise or experience and often at great personal cost to individual aviators, many of whom were maimed or killed in their pursuit of new speed, endurance or altitude records. Although aircraft only saw limited use during the 1914-18 conflict, by the time the war ended many demobilized pilots sought to operate their superfluous ex-military aircraft for civilian purposes and commercial gain.

Most national Governments now recognized aviation's strategic military and commercial potential and viewed post war flying as a socially and economically progressive force that would foster better international relations by promoting cross-border trade and cultural understanding. This utopian ideal was encouraged through the organization of international air meets, air races and the widely reported successes of pioneering long distance flights. In June 1919, pilots Alcock and Brown became the first aviators to successfully fly across the Atlantic Ocean while in August that year the world's first international scheduled flight took off between London's Hounslow aerodrome for Le Bourget airfield in Paris.

The early commercial flights which followed this inaugural service, while being expensive to operate and vulnerable to the vagaries of the weather, nevertheless demonstrated the utility of aircraft for civilian purposes. In August 1919, the delegates of 26 Allied and Associated Powers signed the Paris Convention of which, among other many notable interventions, formally enshrined the right of individual countries to claim sovereignty over the airspace above their territory. In this way, the skies above nations became highly politicized spaces and international agreements were quickly needed to establish the right of an aircraft registered in one country to access the airspace of another. This fundamental shift in the spatial geographies of human activity highlighted the increasing obsolescence of old geopolitical paradigms which were literally "grounded" in the conventions of Euclidean territorial geometry and forced increased recognition that the 20th century would be increasingly shaped by new geographies of the air.

By the mid-1920s, flying had developed into highly mediated and commercialized activity which attracted considerable prize money, corporate sponsorship, media coverage, and public interest. In addition, aviators including Britain's Alan Cobham performed long distance proving flights to the furthest corners of the Empire. In a bid to capitalize on aviation's popularity and stress its public utility to the development, maintenance and policing of Empire, European colonial powers sought to expand their territorial influence through the medium of the air and many pioneering long-distance flights were staged between European capital cities and the furthest-most points of their nation's respective overseas interests.

In addition to demonstrating the nation's scientific and technological prowess, the flights also sought to identify landing grounds and information on the effect of different climatic zones and weather phenomena on aircraft handling and performance. The earliest geographic studies of aviation that emerged in the 1920s thus addressed practical issues concerning aerial navigation, the load bearing capacity of the geology underlying the landing strips, the impact of different weather phenomenon on flight safety, the prevalence of infectious disease at foreign landing sites and the commercial and political viability of new international air routes.

The development of regular scheduled long-haul international air services in the 1930s also necessitated the development of new legal frameworks and international agreements governing the rights of revenue-earning airlines from one nation state to access the airspace of another. During this time, articles documenting the successes of pioneering long-distance flights and the development of aviation in different world regions began to appear. Physical geography, especially as it pertained to topography and climate, directly influenced both aircraft technology and the operation of flights. In equatorial Africa, for example, where suitable land to construct aerodromes was limited, flying boats were developed to permit operations from lakes and rivers while in the Arabian desert, vast ditches were dug into the sand to aid visual navigation and intermediate (and often fortified) landing grounds were constructed to enable aircraft to be refueled and to offer overnight protection to passengers and crew while they awaited dawn and take off the next morning. Such early morning departures were a requirement of flying in desert regions for although aircraft could not yet fly in hours of darkness the effect of the sun's rays warming the sand created dangerous convective activity and turbulence that pilots and passengers alike were keen to avoid.

The outbreak of the Second World War in 1939 and the need to establish military superiority, stimulated significant advances in aircraft design, production, and technology. In Britain, all civilian flying was banned, and attention turned toward military applications. New aircraft systems, together with new forms of propulsion and more sophisticated navigation, surveillance and communications equipment were rapidly developed and deployed with different nations specializing in the production of types of aircraft. This technological specialization meant that the United States, which had long held the lead in terms of aircraft design, focused on the production of large transport aircraft while Great Britain perfected the technique of mass-producing military machines including Spitfires and Hurricanes. Engineers in Britain and Germany were also independently developing new forms of aircraft propulsion which culminated in the jet engine. These engines enabled jet aircraft to fly faster and higher than the piston and propeller aircraft they replaced and after the war ended, they were quickly installed on commercial airframes.

The late 1940s were an important period in the development of air transport geography and influential works that examined the complex interactions that existed between air travel and geography were published. Some of these studies sought to explore how aircraft were expanding the geographic field of vision by enabling people to look down on the earth from the air and, in so doing, gain a greater appreciation of geological processes and landforms and their impact on patterns of human settlement and land use. In 1947, Balchin discussed the "geometrically static" but "geographically dynamic" nature of distance in an era of global air travel in *"Air Transport and Geography"* while Huntingdon (1947) speculated about the future implications of air transport on effecting the

compression of time and space, on global population distribution, cultural diffusion and the spread of agricultural pests and human infectious disease.

The world's first jet powered commercial airliner - the British designed de Havilland Comet-first flew in 1949 and entered passenger service in 1952 and immediately reduced travel times between London and Johannesburg from several days to a couple of hours. The quantitative revolution in the late 1950s and early 1960s, combined with the post-war expansion of air routes, stimulated the publication of a corpus of work that examined and mapped the network attributes (in terms of time, cost and distance) of airline operations. Edward Taaffe (1959) pioneered work into the description and visualization of the new spatiality and urban connectivity passenger airlines were creating and demonstrated the primacy of certain hub airports. The 1950s saw geographers begin to examine the airport nodes themselves, rather than just the linkages between them. Kenneth Sealy (1957) was among those to explore the geographies of airport location and provided detailed descriptions of the physical, economic and regulatory environments in which air transport operated.

In the 1960s, there was a gradual shift away from network-based studies and a diversification of geographic research into air transport which began to explore the effects of time space convergence, global airport architecture and the apparent feelings of "placelessness" the world's major international airports could engender. The advent of Concorde and progressively larger and heavier commercial aircraft during the 1970s, including the B747, raised the issue of aircraft noise around airports while the vacillations and political controversy surrounding the choice of site for London's third civilian airport ensured that issues of airport location, economics, and regional development were placed firmly on geographic research agendas. Geographers were also becoming aware of the potential network diseconomies that could result from there being insufficient airport or airspace capacity to accommodate growing volumes of passengers and flights. However, in a significant departure from conventional quantitative studies, a few geographers began exploring the corporeal experiences of air travel with Borgstrom (1974) in particular writing about the behavioral, corporeal and affective experiences of flight.

By the end of the 1970s, the economic and political arguments favoring deregulation came to dominate academic agendas. In 1978, President Carter's Administration passed the US Airline Deregulation Act which increased market access, revoked tariff setting legislation and removed capacity constraints at US airports. This new regulatory environment had profound spatial implications which included the consolidation of regional flights at key hub airports, the reorganization of airline networks into hub and spoke systems, and the emergence of a new type of airline operator which competed on price, not service, and flew predominately from smaller less congested secondary and regional airports. Geographers were well placed to discuss the changes this regulatory reform enacted, providing details of the geographical implications of new hub and spoke networks for passengers, airports, airlines, and the regions they served. Concurrently, research into individual airports became common with case studies appearing documenting the development and impact of major airports as well as charting the social geographies of local community protest further expansion.

In the 1980s and 1990s, increased attention was paid to the geographies of air transport-a phenomenon which can be attributed, in part, to the founding of dedicated transport and air transport research journals, the increased use of computers (and, later, the widespread use of the Internet for data collection and processing), and the fact that air travel was becoming a common commodity that was increasingly within the financial reach of a growing number of consumers worldwide. Some of these studies focused on the service and network strategies of individual airlines, others examined the role of air service development in the politics of nation building while others explored the socio-economic and cultural contexts in which individual airports operated. Although much of this work, and the scholars who were undertaking it, was published in English and focused on airline networks in in/from/to the globalized "west" a limited number of studies also began to appear which examined the development and patterns of airline services in other world regions which had hitherto been neglected.

Progressive moves toward deregulation, air service liberalization and airport and airline privatization in Europe and other world markets toward the end of the century stimulated the publication of a large body of research in the changing patterns of air service provision in different world regions. Heightened awareness of the epidemiological and environmental implications of mass aeromobility was also becoming increasingly evident but it was growing awareness of the social dimensions of air travel, forged in part thanks to the "mobilities turn" in the social sciences at the turn of the millennium, that helped to usher in a new era of contemporary air transport geographies.

The Contemporary Geographies of Air Transport

In his discourse on the geographies of mobility, Cresswell (2006) considered the metaphysics of movement in Western social thought and argued that an historical sedentarism suspicion about mobility has been largely superseded by a new global nomadic overview in which hypermobility is the norm. Such flows, whether material or virtual, real or imagined, were seen to circulate around the globe, often spilling over the dams and defences of firewalls, immigration controls and customs inspection posts that were designed to impede their progress. The use of such hydraulic metaphors demanded theoretical perspectives that can comprehend these new "geographies of flow" which are attuned to the high levels of mobility-or hypermobility-which had come to characterize the modern world.

In light of this increased attention to questions of movement, sociologist John Urry (2000) argued that there was a "mobility turn" spreading into and transforming the social sciences which was characterized by a newfound focus on the ways in which the social world is shaped by the global networks which transmit flows of people, goods, money, and knowledge. For geographers, this

enabled new explorations of the airport terminal as a site of spectacle and spectatorship, the aircraft cabin as a place of fear and fascination and the airspace in which aircraft fly as a highly politicized and social realm (Adey et al., 2007).

Although it has been claimed by some that the paradigmatic modern experience is that of routine rapid mobility over long distances, it is important to note that this is only applicable to a relatively small number of the global population and thus it cannot be considered a truly universal experience as not all members of the global community are equal participants. As Massey (1996) has explained, the time-space compression that air transport has affected is highly uneven and exhibits a distinctive "power geometry" in which individuals and particular social groups are either emancipated or marginalized. The contemporary geographies of air transport are thus highly socially variegated, and both reflect and reinforce discourses of political power, monetary wealth and social privilege. High levels of personal mobility by frequent flyers must be juxtaposed against the spatial inertia and inaccessibility of the less affluent. Here, issues of race, ethnicity, citizenship, gender, age, and mental and physical dis/abilities conspire to enable or restrict particular forms of mobility.

Viewing air transport through a lens of social and cultural theory as opposed to economic and technological rationality has alerted geographers to some of the key issues of power and identity that adhere to different spaces of mobility. Indeed, it has been argued that commercial air transport provides one of the most highly visible articulations of global power and the influence of the state. The airport, as a gateway to a nation, has long been a target for terrorist activity and, consequently, the terminal has developed into a place of constant surveillance. Signs and recorded security announcements continually reiterate that passengers are being watched, classified, sorted and screened. These trends are manifest in programs and procedures that employ biometric technologies, artificial intelligence and the cross-border exchange of passenger information which work to facilitate the rapid mobility of "known" and "approved" travelers but purposefully delay or deny mobility to others.

The plight of thousands of airport employees who perform the necessary but repetitive, mundane, poorly paid and often hazardous cleaning, construction, maintenance, and security activities in the terminal has also been brought into sharp relief and their experiences of shift work have been contrasted with the hypermobility of the passengers they serve. The different practices and technologies that create these inequalities of work and access bestow particular emotional attachments for individual airport users. The supposedly "placeless" realm of the international airport may, therefore, be variously experienced as exciting, stimulating, stressful, tedious, disorganized, overwhelming, oppressive, frightening, welcoming, thrilling, frustrating or soporific and trigger a remarkably diversified range of inhabitation.

The debate surrounding the role of "place" in contemporary air transport geographies poses important questions about how "local", regional or national identities are projected onto the global stage. The name and corporate identity of individual airlines, particularly full-service flag carrying airlines, are often intimately tied to expressions of national identity and belonging while major airports are often named after famous local citizens, with politicians, composers and sporting personalities being particular popular choices.

One of the most widely noted characteristics of contemporary air transport is its seemingly inexorable expansion. Despite occasional external shocks temporarily depressing passenger demand, the number of flights and passengers is increasing year-on-year, generating new demand for airports, runways, and air routes. Despite significant concern about the implications of such expansion on the global climate, many aviation futures are being contested at the local level by those concerned by the noise and emissions generated from enlarged and expanded airport operations. Anti-airport expansion campaigns and flight free holiday movements are growing in influence as citizens articulate their opposition to unfettered airport expansion.

Geographers have consistently identified the emergence and expansion of air transport as being one of the key drivers of globalization and a key enabler of social inequity. They have used aerial photographs to map the surface of the earth, data on air traffic flows to delineate the morphologies of air transport networks and identified the social and cultural dimensions of a technology that seamlessly binds important global cities together in an ever-tighter web but leave many other more peripheral spaces only loosely connected.

As we sit here with our crystal ball to write this chapter, we think back to not much more than 100 years ago when the technology for powered flight technology was just taking off. Prior to then, human flight had been a fantasy of Icarus or a risky and unpredictable experience in a balloon. But in that touch more than 100 years, we have flown many times faster than sound, flown into space and have taken control of light like no other species, incorporating it into our way of life. As evidenced over this time, aviation is a rapidly changing and always developing sector, bringing with it substantial impact on many facets of our society. The industry has grown to such an extent that today if measured as a country in terms of generated GDP it would be with 65 million supporting jobs and \$2.7 trillion in global GDP the 21st largest economy in the world (IATA, 2019). While its significant economic, social, and cultural impact has been shown across both city and for rural and regional communities (Baker et al., 2015), the recent debate also includes negative externalities, most notably its carbon footprint (aviation contributes 2%–3% of all carbon emissions globally; European Commission, 2019), as the awareness and urgency of climate change action grows.

So what will the future bring? Notwithstanding the mistiness that grows on the horizon as we look further and further forward, in the future we can see, technology, policy, and new operating models will drive change to air transport, continuing on its trajectory of disruption and growth (demand for air transport has doubled over the last 15 years, see Airbus, 2019). There are various segments of the air transport sector, with some more mature than others. As with Airbus (2019), we argue that air travel will continue to become more and more accessible connecting more and more places and people through new forms of interconnectedness. Environmental policies and agreements such as CORSIA will continue to develop to help manage the carbon costs created by air travel, and big data along with digitization and automation will revolutionize how, what, and when passengers are marketed and serviced to and how their services are delivered. In that context, pure airline operations will remain fundamental yet increasingly smaller functions within large and potentially multinational enterprise that are focused on providing customer centric mobility and logistics services. And finally, new air transport developments will happen outside of the airline space. Drone technologies, which are currently in an embryonic stage of development, will transform how we go about our daily lives in cities, both from a freight and passenger perspective, as we make use of the third dimension in fascinating new and more integrated ways.

The sections of this chapter are structure in a way that aims to provide a comprehensive overview of what we think the future of air transport may look like. Starting with a section on strategies around improved connectivity and deeper integration of the travel value chain, we will then discuss issues around sustainability in the light of an ever-growing aviation industry followed by a section on big data. The chapter moves then on to an evaluation of future governance and regulation scenarios which is followed by more detailed thoughts around air freight and the evolution of drone eco-systems. We conclude the chapter with some innovative thinking around technologies and strategies that will get the air transport industry to the next level.

More People, More Places—More Integration

As we move ourselves to new places around the globe, we reposition ourselves, moving our knowledge to be used for new purposes, exposing ourselves to new cultures and connecting us with new people and places (in the future most likely beyond our planet and into space). Air transport originally formed point-to-point connections between two places, where people were and where they wanted to be. But over time airlines have worked together to make new connections for their customers. Through interline, codeshare and joint venture agreements they have built virtual, shared networks making connections with their peers and strategic alliance partners to deliver more options and seamlessness for consumers both in passenger and freight operations. Initial steps to connect even more destinations into these networks through rail services has had middling success however it has opened discussions about how coordination between operators should be facilitated past the airport departure and arrivals lounge (Merkert and Bushell, 2019a). But pressures on congested airspace will continue to grow, consumers will want more integrated choice (Chowdhury et al., 2018), and

environmental concerns will be privatized into airline cost structures through carbon trading mechanisms (with CORSIA being a first step into that direction). Accordingly, we expect to see refocused effort on these coordination problems to more successfully integrate rail and airline services in the immediate future. This may also require the reformation of rail, bus (and in some ways taxi) operators to reposition them commercially and competitively, to encourage partnerships to develop between different transport operators to develop solutions that are better for everyone, and not just the operator involved. This may be connected with land transport pricing reform (i.e., road user charging—for both road operational and maintenance costs as well as congestion) where all users of the land transport network need to think differently about how they use it most efficiently and will also be impacted by the rise of automated ground vehicles (most likely electric propulsion) in particular for the last mile trip or delivery. We further argue that such integration will further assist airlines and other mobility/logistics providers to overcome the likely disruption due to more frequent and increasingly severe bad weather events (as part of global warming).

From a network strategy perspective, we foresee that the hub and spoke model will continue its decline but will maintain use in select cases, focusing on regional distribution and the major, volume based and cost sensitive trunk routes of bulk carriers of the Middle East and Asia. Connections will continue to be built between origin and destination points and airlines will downsize their routes to match the right aircraft to the right route, which is what customers want (Johnson et al., 2014). Longer and thinner routes will be opened to meet the needs of consumers with Qantas' ultra-long-haul (ULH) project Sunrise being first evidence of that development. This "hub busting" service will seek to bypass competitor hubs (e.g., Singapore Airlines, Emirates and others) and charge a premium to do so, offsetting the costs associated with operating such a long flight. In itself this also represents an interesting market segmentation exercise, with Qantas looking to serve those customers it can do so profitably, instead of fighting a losing battle against the hub airlines with better-cost economics. Aircraft manufacturers will need to match these demands and developments of smaller aircraft that are less risky to fill but more capable in terms of reach will be required.

In a more micro sense, congestion in cities will drive other decisions. Airports are significant generators of urban trips and growing airport usage will increase pressures on urban transport networks. Greater integration into extant public transport networks will be required, through for example better connections of airports into their networks. This may take the form of better terminal design, positioning trains, and buses inside or near airport terminals to link directly with passengers going to or coming from flights. Other integrative measures such as better trip information and linked air and ground transport fares may be investigated. Though ground transport industrial reform may also be required to address competitive issues like the reliance of airports on car parking revenues, and the dominance of taxi and ridesharing services in ground transport services, the entrenchment of which prevents the development of more efficient transport options may need resolving.

For further discussion, see 10021: Demand for Passenger Transport and 10076: Competition of Air and High Speed Rail.

Improving Footprint, Enhancing Sustainability

Integration and providing more service to consumers is a sustainability measure insofar as preserving consumer value leads to financial viability, including in regional contexts. But of course, sustainability is also about the traditional sustainability focus areas, including carbon emissions and noise management. While it has been a significant topic in the early part of this millennium, environmental issues continue to be an area of focus for airlines, if not (at present) the wider political landscape. Recognizing that there does remain (and currently growing) a latent consumer preference for positive environmental activity and that air transport is a significant contributor to environmental damage to the atmosphere, air transport operators are still focusing on the impact they have. Now some of this is in obvious self-interest—reducing fuel consumption not only helps reduce the emission of greenhouse gases but also reduces fuel bills and the overall exposure to the risk of very volatile jet fuel prices (Merkert and Swidan, 2019)—but some of it is definitely a response to consumer preference, for example the recent trend to swap plastics out for other materials for in cabin items. But clearly some of this is driven by airlines wanting to at least appear to be good corporate citizens in the eyes of consumers, no doubt due to the desire by air transport operators to earn social licenses and derive the benefits that these deliver.

As mentioned earlier, future steps to better integrate ground transport into air transport operations are likely and may form a part of sustainability strategies across the industry. However, managing the substitution effect (i.e., increased potential for long-haul flights as a result of increased rail journeys making slots at airports available—e.g., Chiambaretto and Decker, 2012; Janic, 2011) is also needed. Airlines will continue to work as an industry to design their own emissions management program. At an individual level, air transport operators will continue to look to offer voluntary offsets for consumers to purchase as an add on (or in some cases bundled) good.

Though sustainability is not just about the environment. Air transport sustainability has come along way in the last few decades as airlines have been positioned as commercial entities in their own right, and not departments or agencies of governments provided for national interest (though many of these still exist). More and more commercial focus will be required to ensure that airlines can keep reducing the cost curve and keep ahead of declining revenues. Some operators are beginning to better identify consumer demand and are unbundling and bundling products to not only improve margins but also deliver what consumers want in a journey. This will continue to occur with more and more ancillary revenue generated through identifying what consumers want in and related to a flight, and what they want to buy. And the further development of low-cost carriers, into ultra-low-cost carriers, represents a different way of achieving sustainability, by reducing resource consumption further. However, this needs to be balanced with the lower price of flights leading to more overall consumption, and questions are being asked if the debundling of these services and management of them by the consumer is actually leading to lower journey resource consumption (as passengers need to get to far flung LCC airports from the city), or if the disaggregate journeys are more resource consumptive.

Perhaps one of the biggest changes, and for us one of the more opaque and unclear ones, is the future of power generation for the sector. We have had jet engines for close to 80 years now, in various formats, which in reality are extensions of earlier piston engines, which are still used across many aircraft types today. But these appear to be reaching technical limitations, with their further capability expansion limited by both engine and airframe design. We expect that alternative and renewable fuels will see more and more research and deployment as fuel costs continue to rise and more demand for less environmental impact increases. However, there will come a time where brand new ways of propulsion will need to be considered to support air transport growth. What is the successor to the jet engine?

For further discussion, see 10085: The Economics of Reducing Carbon Emissions from Air and Road Transport.

Big Data, Better Decisions?

Air transport operators and other players in the aviation supply chain have been collecting substantial volumes of data for as long as the industry has been in the air, given the relatively advanced state of technology used to collect this data. Aircraft engine manufacturers collect more data than any other industry with for example Pratt and Whitney (McKinsey & Company, 2019) generating 355 Petabytes per day (in comparison, on a daily basis Google processes in total 24 Petabyte only). We argue that in the future, even more data will be collected and analyzed for brand new purposes. Airlines generate so much data that they increasingly wonder why not become better in using it rather than leaving the floor to consultants, aircraft/engine manufacturers, and/or technology giants such as Google or Microsoft.

Big data is being used operationally, measuring climate (especially winds), aircraft performance, and a range of other variables to better design flight paths to reduce fuel consumption and travel time. While big data analysis in airline network planning is becoming somewhat matured now (Hausladen and Schosser, 2020), the intensive use of big data for consumer management has been a more recent development. Right now, airlines are building consumer profiles through their frequent flyer and corporate loyalty programs. Using the attraction of free flights, lounge access and other benefits, these programs are being used to generate nonairline revenue and the data collected is being used (in addition to selling it to or collaborating with data aggregators and retailers) to understand more and more about what and when people buy and at what price. Travel agents are being bypassed in preference for direct sales that airlines can control, and own the data generated by their customers (Fiig et al., 2015; Madalozzo and Fernandes, 2016). In perhaps a more interesting technological development, big data is also being considered to change the way airline pricing is generated, and in the future it may be the case that instead of having the multiple airfare classes we use today, individualized fares (perfect price discrimination) are made available for each passenger as they book, to deliver the flight they want at the best fare they are willing to pay. Through concepts such as blockchain, big data networks are also being used to increase data security, protecting individuals and companies alike from harmful attacks.

However, big data is limited by how it is harnessed. Across all users of big data, including airlines, more needs to be done to link big data sources so that the data can be interpreted (which may be difficult in the context of privacy concerns) and used instead of just collected and stored to gain electronic dust on the shelf. Information technology systems as we know them now need to be reconsidered and newer, more holistic approaches to data will be developed in the future. These systems need to not only reduce the interface issues between data sources and calculations/algorithms that use them (for example risk of human error while migrating information between systems), or subsequent planning, operational and reporting information flows, but also need to be able to highlight new data relationships that can represent efficiency/productivity gains and potential new markets.

Of course, the human element is significant in driving the reengineering these systems and air transport operators need to become more skilled at data management, more so than they are now. Indeed, some transport operators in other sectors are viewing themselves more as technology companies than transport companies, which while may be an extreme, is somewhat reflective of the direction that airlines will find themselves in. Management strategies may in the future need to be more encompassing of incorporating indicators that big data analysis can measure. Whether these are at top line levels like return on capital invested measures, or as subsidiary measures will depend on how significant the measure is to airline success. Overall, we see harvesting data being a strong trend in airline management, which will result in the actual operation of aircraft becoming a less and less important part of commercial viability of successful air mobility/logistics providers.

As with all big data exercises, however, there will be a point, where from a sustainability perspective, airlines will have to decide when a line needs to be drawn, and that some consumer behavior is best left unknown. While consumers are happy to trade their consumption behavior for more flights or more customized products, social responsibility suggests that big data holders, including airlines, will need to recognize the power they hold and manage this appropriately, lest it cause a case for policy intervention.

For further discussion, see 10222: Information Sharing and Business Analytics in Global Supply Chains.

Policy and the Rules of the Game

Air transport policy has seen substantial reformative change, and particularly at the international level, significantly more so than other forms of transport as governments have liberalized air services and routes, and have privatized state-run airlines. This pattern of deregulation is likely to continue where there are clear benefits of doing so, despite current protectionist tendencies. Though there is unlikely to be a rash of government owned airline sales, there will probably be some more collapses or significant restructures to

decrease airline size and activity to reduce government exposure. With airlines increasingly focused on mobility/logistics service provision and data managers there is scope for further regulatory change, particularly around national ownership rules and (bilateral) air service agreements. And just to go crazy for a minute, imagine a world where Uber provides future airline like services similar to those of American and Qantas in the future. Most probably not possible given the governance structure of aviation and the role of defense in all of this but who knows? What is more likely is that future policy decisions in the land transport sector will have more impact on the air transport than direct policy change in the air transport sector. Despite the hub and spoke model being under pressure from more point to point connections, the air–rail experiment may continue if rail operators are liberalized, giving airlines more options to work with on the ground. In Japan and Europe, introducing more competition into rail markets may provide the commercial impetus for partnerships to develop to make air–rail connections more attractive to consumers and also more viable, through encouraging new service pricing and integration (Merkert and Beck, 2020; Merkert et al., 2019). More direct regulatory measures may be taken in other jurisdictions like China.

For further discussion, see 10074: Airline Economics and 10075: Privatization and Deregulation of the Airline Industry and 10436: Airline Regulation

Air Freight, Slower but Cheaper?

In another less than clear vision, we see that air freight could see potential change. Freight has traditionally been more of a by-product of air passenger transport, utilizing available space, though some all freight carriers have arisen and some passenger airlines have established all freight arms (Merkert et al., 2017). However, experiences in other transport sectors show that maybe there are new ways of doing air freight that may see development. Freight, particularly consumer goods, between Asia and Europe has traditionally been carried by ocean going ships, with small, high value and/or time sensitive consignments carried by air (Alexander and Merkert, 2017). Recent rail developments have seen new transport options however with through trains from China to Europe, offering a faster trip than sea freight, but slower than air. Which freight consumers seem to be liking given growth in this sector. This suggests that consumers are willing to sacrifice time to save cost. We may see similar developments in air freight markets. From developing services that take longer to deliver, and perhaps even involving specifically designed aircraft which consume less fuel, air freight could expand its market through lowering costs, particularly in the presence of greater package delivery. We also expect to see air freight transport embrace pilotless technologies before passenger freight services do, arguably due to the public perception of safety and security which is seen to impact passenger far more than freight services.

For further discussion, see 10270: Air Freight Logistics and 10283: Eurasia Rail Freight, Enables and Inhibitors of Future Growth.

The Drone Revolution

The last but potentially greatest future for air transport is the impending revolution that we expect to see brought by drones (Merkert and Bushell, 2019b). Quite unrelated to airlines (other than having the potential to disturb their air space), new air transport markets in urban areas may become possible as the small airborne devices allow for new transport services to be offered (for a detailed literature on this see Merkert and Bushell, 2019b). Dry cleaning pickup, delivery of food, and delivery of that one thing forgot to get that one thing at the shops. Though in many cases this last forgotten delivery may not have been necessary as you may not have even been to the shops in the first place—it may be that you can order all of your needs online and have it all delivered to your door, balcony or other suitable drop off location. This will have obvious consumer benefits though it will no doubt have impacts elsewhere in the economy. What might it mean for retail stores and the retail supply chain? What might it mean for road congestion if air journeys replace road couriers? What might it mean for the social functioning of a society that now does not need to go out as much to shop or run everyday errands? What will people do with the timesavings? Or will cheaper transport options increase total package delivery, much like ridesharing has increased road usage? What if those drones are unmanned? What will happen to today's truck, bus, and train drivers? Will they all be upskilled? It seems clear that this revolution is going to require new management approaches and possible policy intervention. Furthermore, managing so many of these small flights in congested airspace will require new technological solutions and ways of managing the airspace efficiently and safely. Discussion has commenced about how Low Altitude Airspace Management Systems may extend controlled airspace down from current levels to incorporate drones into the extent airspace management system (Merkert and Bushell, 2019b). At this point, it seems fair to say that a future of drone operations will be more complex but also more exciting in terms of opportunities that it will create. As usual innovation should be embraced and supported by public policy wherever possible.

For further discussion, see 10004: The Future of Urban Freight, 10093: How will autonomous vehicles impact car ownership and travel behavior for more discussion on this, and 10272: Drones in freight transport.

Beyond the Barriers

Flight has always been challenging barriers, from the barrier of the third dimension itself to various speed and endurance records. And there are more barriers to be breached, with the speed and gravity barriers being key focus areas. We have been past the airspeed

barrier before, with the Concorde providing faster than sound travel, though we retreated from this in the face of increasing fuel prices. But it will come a time where we push past this barrier again, as we seek to reduce travel times more. ULH flights as operated by Singapore Airlines, Qantas, and likely others can only do so much at their speeds that are just under sound, but eventually consumers will reach a point where they will pay more to arrive at their destination sooner and make more productive use of their time.

Perhaps most interestingly from the perspective of the wider community, it may be that air travel will lose its air component as it moves beyond the atmosphere and take us into space. Now, whether this is in the remit of this chapter or not, this exciting new development does represent an extension of air transport and represents brand new potential for the sector. Currently, space flight is being pursued as a project to provide flights to the wealthy, but no doubt it will move past this as the cost curve of the technology falls and it will provide flights to a broader range of the public and even to freight services. Now this might be a way to provide faster point-to-point services, and a few-hour trip from Sydney to London might be possible. Space flight might be the successor to the jet engine. Though this will also lead to altogether different destinations and into destinations that have to this day been the domain of science fiction only.

Final Observations

Air transport is already a highly developed and advanced industry but as we have shown, it has plenty of latitude and room for growth. The future for some sections of the industry are quite mature and in the absence of any significant disruption, such as transportation beam devices, these segments will continue to mature and refine their current operation. Now, this hypothecation is just one view of a set of possible future events. A great many things may impact this view, especially if our society experiences changes that are not within our foresight. But regardless of this, changes in aviation and air travel and the expanding use of the third dimension will continue to impact on us and our development as a society with many intended benefits but potentially also a number of unintended outcomes. There may also be a future where transnational air mobility and/or logistics providers with aircraft/air borne vehicle operation will become, while continuing to provide services as the safest mode of transport, a secondary function of successful and consumer centric and data driven air transport management.

Introduction

Air transport keeps growing and will continue to grow. But it grows in a highly variable way, according to the territorial distribution of demand. The variability of demand depends on several factors. The first is indeed the distance between the origins and the destinations that the demand wants to connect. Distances to be covered depend, in their turn, on the size and the shape of the countries involved and vary of course if mobility is global or intercontinental, continental, or national. A second factor of demand variation is the development level of the places that are origins and destinations of any transport connection: rich and developed areas are likely to generate a higher volume of demand than poor and less developed areas.

A third relevant variable in determining demand for mobility is its motivation: to simplify, as far as passengers are concerned, business or leisure (Graham et al., 2008) represent two very different segments of demand, as well as freight transport does.

A further factor—of a territorial nature—in driving mobility is the so-called “catchment area” of the infrastructure (airport, station, port) that allows the departure of a trip or a travel. It will depend on its accessibility and on its transport function: in the case of air transport—on which our attention is concentrated here—what matters for example are the characteristics of the airport (hub, point-to-point) and the frequency of the flights it generates (regular or episodic, as in the case of touristic charter flights).

This paper is structured in eight short sections. The first deals with the relevance of the territorial scale in air transport. The following section analyzes the “spatial” determinants of demand for air transport. Then, the vertical integration between airports and airlines’ services is discussed. The fourth section underlines the impacts of airports on the surrounding territory, followed by the issue of “accessibility” to airports. The spatial implications of the management of airports are dealt with, followed by the discussion of the “natural monopoly” characteristics of airports. Finally, the specific issue of the “generalized cost” applied to air transport is presented.

The Relevance of the Territorial Scale in Air Transport

The “territorial scale” of air transport depends on these variables, indeed strictly interdependent on each other (Mukkala and Tervo, 2013). It may be noted that in the case of air transport—as well as in the case of other transport modes, such as road, railway, or water—the territorial scale is relevant from a double point of view: the infrastructural one (location, catchment areas) and the services provided by the infrastructure (connections, motivations, frequency). Any approach to air transport analysis implies to keep in mind that air mobility is only allowed by a strict “vertical integration” (see below) between these two phases or aspects that cannot be separated (Fu et al., 2011). The analysis that follows examines in turn the variables that allow to understand the spatial (territorial) implications of air transport.

The first factor that determines the demand for air mobility is the distance that separates any origin and destination “couple” that must be connected. It may be observed that these distances may not be covered necessarily neither by a unique mode of transport nor by a direct connection but through a multimodal (road, rail, air, water) and networked transport system. It is obvious that distances between origins and destinations heavily affect the modal choice.

At the extremes, bicycles will be chosen for short distances, air for very long distances. For medium distances, road and rail will tend to prevail, although there is not a clear cut “market” separation among transport modes as far as distances are concerned.

Modal competition in fact generates overlapping of the spatial market share of different transport modes. In addition, the growing trend of multimodality to satisfy complex mobility demands further complicates the identification of the most frequent distance covered by different modes. However, a sort of rule of thumb states that air is seldom used below the distance of 4–500 miles.

Having said that, it is evident that intercontinental/international mobility, above the threshold of 400–500 miles, is usually met by air, with an increasing competition played by high-speed rail. As far as international mobility is concerned, the relevant variables to be taken into account are the size and the shape of the countries involved. In large countries (such as USA, China, Russia, Brasil, Australia, to cite only a few) air mobility keeps being privileged (always beyond the cited threshold) (Wittman and Swelbar, 2014). But also in countries whose shape is “long” (such as Italy, Germany, Argentina, India) air transport is indeed the preferred transport mode. On the contrary, international flights will not conquer any market share and compete with other transport modes in small countries or in islands (the Baltic countries, the Netherlands, Belgium, Malta, Cyprus, Island, Ireland to cite only European countries).

An almost trivial conclusion is that geography matters in the identification of the role of air transport in meeting spatial demand for mobility.

The development level of origins and destination of air transport is the second relevant variable in ascertaining its importance. Air transport tends in fact to be a concentrated phenomenon, due to the fact that airports—of different size and role—play the fundamental role of being the places for take offs and landings. Therefore, they are located in areas—mainly close to large cities and metropolitan agglomerations—where inward and forward demand is concentrated (Blonigen and Cristea, 2015; Sheard, 2014). The fortune of air transport is therefore strictly linked with sites that show a high level of economic and social development. It is likely that development occurs—more and more frequently—in cities, the places where innovation and a great socioeconomic dynamism take place nowadays. It is well known that urbanization is a process that the world is facing today and will probably face in the future. On the other hand, large cities and metropolitan areas are growing in size and therefore provide a significant market for air transport. The combination of the level of development and of the size of spatial agglomerations drives the location of airports in their proximity as they serve dense “catchment areas.” A potential conflict for these locations is raised by environmental problems, as take-offs and landings of airplanes cause indeed air and acoustic pollution (external diseconomies). In some cases, creative solutions have been achieved, as in the case of the Kansai airport (Osaka) where the airport has been located on an artificial island, some twenty miles in the sea, linking through a bridge the city with the airport. For the same reason, in some large metropolitan areas, more than an airport serves its passengers (and freight), one being located within the area and the other at a certain distance from downtown. This is the case, for instance, of Milan (respectively for Linate and Malpensa airports); of Paris (Orly and Charles de Gaulle); of Tokyo (Haneda and Narita).

The “Spatial” Determinants of Demand for Air Transport

Demand for mobility is very differentiated according to its motivations. As far as passengers are concerned the two main drivers of demand are indeed business and leisure, with different roles played by the time length of planned mobility. Easy examples are represented by the fact that short “business trips” tend to use the quickest modes of transport that help saving time. Combined with the distance and agglomeration issues already commented, the quickest competing modes are air and high-speed rail. On the contrary, longer business trips will tend to favor the most efficient and comfortable modes, as the incidence of travel time is less relevant. For leisure mobility, the arguments are similar but do involve also other transport modes, such as road or even sea (it is the case for cruises). The territorial scale of the catchment areas, in both cases of business and leisure, also varies according to the lengths of the trips. When short trips take place the closest airport to the passenger is preferred and therefore the catchment area tends to be smaller because proximity matters. When longer travels are planned, the passenger will try to reach the airport that presents the highest range of connections: in this case the catchment area of the chosen airport may be very wide and imply a multimodal access (either by road or by rail). The hubbing function of the airport (see below for the concept of hub) may further increase the size of the catchment area of the airport that provides a wider choice of routing to achieve the final destination.

Air transport—for some intermediate and final products, generally speaking of high value, relatively small size and that needs a rapid delivery—serves also the mobility of freight. Transporters of good that will inevitably use the road mode for the first and last mile segment of the overall movement will be confronted with the choice of the closest airport for quick access and the airport which serve a wide network of destinations. The strategy of the logistic operator—that includes time and distances from airports as relevant variables—will therefore affect the role of air transport services (Button and Yuan, 2013).

It is evident also in the case of freight mobility that territorial scale is a relevant variable for the competitiveness of air transport. Again, the areas with a high concentration and development of manufacturing production are likely to be those that present a major role in air freight transport.

The concept of “catchment area” has been frequently referred to as the area from which airports (the infrastructure) and services (the air connections) served by airports attract and capture their market, both passengers and freight (Mellander and Holgersson, 2012). Its width and intensity of attraction depend on several factors. In addition to those already hinted to—demographic and production concentration; level of “local development”; different motivations in demand for mobility—there are other factors that contribute to identify the catchment area of an airport.

The most important is accessibility, which concerns both a spatial and a time dimension. From the spatial point of view, an airport is “accessible” if other infrastructures allow to reach it; that is, if the road and railways systems may convey traffic to it. Airports

that show the widest catchment areas are those that lie in the gravitational center (poles) of capillary networks of roads and railways and act as main “nodes.” Roads and railways may compete between themselves to bring passengers and freight to the airports, but they are only a necessary but not sufficient condition to define their catchment areas. In fact, accessibility is not granted by the sole existence of the “feeding” infrastructure: it will also depend on the services that will be provided. If roads leadings to airports are congested, for example, times to reach the airport risk to be too long and uncertain for private cars and public buses (especially during peak hours). In that case, railways will be favored, but only if the frequency of their service is sufficiently high, punctual, and well scheduled. Sometimes, as far as railways are concerned, these services may be provided by dedicated shuttle services; or being inserted in medium long distance networks with a specific stop in (or underneath) the airport (such as in Paris Charles De Gaulle, Amsterdam, Narita, Rome) to facilitate the multimodality of travels and accessibility.

The spatial distribution of potential users of air infrastructure and services, of course, may not be uniform: it may occur in concentrated areas or along directions/lines (East-West or North-South), to simplify. In this last case, the road or railways infrastructure that give access to the airport will “shape” the catchment area in a much simpler way (such as in the case of Lyon, Bologna, Zurich) and reduce the investments in providing to airports a networked system of accessibility.

Catchment areas of air transport infrastructure and services—due to all just made considerations—may obviously partially or totally overlap. The distances among the locations are thus relevant: the overlapping may be partial if airports are sufficiently distant from each other; or almost total if their location is within the same metropolitan agglomeration: the main example is London, where Heathrow, London City Airport, Gatwick, and Stanstead serve almost the same potential spatial market.

The London case is a very good example for a further consideration. Demand for air mobility may indeed cause the overlapping of catchment areas from the geographical point of view. However, from the functional point of view, the four airports in London play a different role. To simplify, Heathrow is an international and intercontinental hub airport, while other airports play either a role of European hubs or a role of point-to-point connections both at a national and continental scale. A hub airport is an airport that receives feeding flights from different origins and forwards the passengers to different destination, playing a “sorting” function at different territorial scales: the intercontinental one is the most desirable for air companies that are thus able to fill the most expensive long-distance flights and fully exploit their seat capacity. But a minor hubbing role may even be played at the continental (North America, Europe, Asia), or even at the national level (Chicago in the United States, Rio de Janeiro in Brasil, Orly in France, Frankfurt and Munchen in Germany, Fiumicino and Malpensa in Italy).

A point-to-point airport, as the word says, is an airport that connects directly one origin with one destination.

The different role, from the territorial point of view, is self-evident. In the hub case, airports benefit from a very large catchment areas, while in the case of point-to-point connections the catchment area tends to be more local and limited.

The Vertical Integration between Airports and Airlines' Services

Big air companies—due to the “vertical” integration of air transport between infrastructure and services—tend to concentrate their activities in hubs of intercontinental range, because it is convenient from the economies of scale point of view: in hubs they can in fact locate the “maintenance” and operational activities of their fleets of airplanes (Homsombat et al., 2014). To give some examples, Air France, exploits the hub airport in Paris Charles De Gaulle; KLM in Amsterdam; Alitalia in Rome Fiumicino; Lufthansa both in Frankfurt and Munchen; British Airway in London Heathrow; Iberia in Madrid; Some worldwide companies establish their hubs of reference also in different continents, such as Delta, which is based mainly in Atlanta in the United States and in Amsterdam Schiphol and Paris Charles De Gaulle in Europe; or as Qantas in Sidney and Dubai.

In identifying the main hubs, one must take into consideration also the differences existing between regular airlines and low cost companies. These are companies that try to meet air transport demand at very cheap tariffs, to capture the market of low income, potential users (young people above all) that still want to use air for their mobility. They operate mainly in the leisure segment of demand, with an increasing share also in the business segment; provide mainly a point-to-point service; are able to keep costs (and tariffs) low due to the reduction of accessory services to their customers and mainly online booking. They tend to serve only the intracontinental demand for air transport as this allows to increase the efficiency of their operations (e.g., number of flights per day of the same plane).

Low cost companies have rapidly increased their market share in all continents. The largest ones are Southwest Airlines in the United States; Ryanair and easyJet in Europe; the Air Asia Group in Asia with several millions of passengers served every year. Their operational hubs are respectively in Dallas; Dublin; London Gatwick and Malpensa; Kuala Lumpur.

When dealing with the territorial implications of the vertically integrated (infrastructure and services) air transport activities, one must also take into account the locational attraction of economic activities in the proximity to airports (gravitational effect) and the impact that air transport exerts on a more or less wide extension of the territory surrounding airports.

Playing on words, one might say that the “scale” of air transport (size of airports in terms of number of connections offered and volume of passengers and freight moved) is highly correlated with the “scale” (extension) of the territory affected (Redondi et al., 2013). Such a correlation is the outcome both of a centripetal and centrifugal effect. The bigger is an airport the larger is the attraction of firms (Beifert, 2016) desiring to locate in its proximity, either on site or off site, that is within the airport area or nearby the airport area. Headquarters of firms, or even production factories, stores and logistic activities—especially if the airport plays a hub function—are interested in locating as close as possible to the airport to reduce times of access to the airport and its connecting services to a wide number of destinations (markets, for the firm) for managers, employees and freight.

In some cases—one very relevant example is Amsterdam Schiphol—this has given rise to big real estate developments “associated” with the airport. It is obvious that this attraction effect is not so relevant in small or point-to-point airports of small size and providing only few connections: economies of scale, neither from the airport point of view nor from the territory involved, do not play a significant role in these cases (Freestone and Baker, 2011).

The Impacts of Airports on the Surrounding Territory

The “centrifugal effect” of airports on their surrounding territorial scale is captured by impact studies (Allroggen and Malina, 2014; Button, 2010). There are consolidated methodologies—for instance provided by ACI Europe and several case studies, such as the one for the Malpensa airport—that outline how to evaluate this effect. Impacts may concern totally new (Tveter, 2017) or additional investments (for instance, new runways or terminals) (Breidenbach, 2019) as well as management of services impacts: through complex methodological techniques—such as input—output analyses—it is possible to estimate the direct, indirect and induced effects of on site (including the role of air companies operating in the airports) and off site impacts on generated turnover, value added, employment, imports by investments, and current expenditure. Some studies estimate also the fiscal impacts.

Direct impacts measure the effects of the expenditure directly made for purchasing goods and services during the construction or the management phases; indirect impacts are those that are generated by firms directly implied through the procurement of goods and services that they must meet in their turn. Induced impacts are the effects of consumption expenditure made by the employees of the firms directly and indirectly involved in the construction or management phases. These complex estimates allow to measure the “multipliers”—often significant—of each dollar spent for new or additional investments. The range of such multipliers is between 1.4 and 1.8 in most cases. Of course, the territorial impacts may be very concentrated in the area of the airports—if its economic structure is highly diversified—or present some dispersal (leakages) effects if the structural economic features of the area are weaker or less interdependent. The territorial scale of multipliers will therefore depend on the development level of the area in which the air transport activity is high (as in developed metropolitan areas) or low (as in less developed or still developing areas).

Accessibility to Airports

An important effect on the territorial implications of air transport is played by “accessibility” to airports. Accessibility is defined as the easiness with which incoming and outgoing passengers and freight may reach an airport with different modes (road and/or rail).

Accessibility may be evaluated in terms of existence of infrastructure and their level of services (congestion), both of which contribute to the amount of time needed to reach or leave the airport. In particularly dense metropolitan areas, road (with private cars or with public bus transport) and rail (with the regular network or with dedicated shuttle service) compete with each other and provide to air transport users alternative modal choices. Given the competition in trying to increase the modal accessibility of airport to the surrounding territories, it is not easy to define a unique “model of connectivity” of rail compared with road, which maintains a significant prevalence in this particular “market.”

However, examining a certain number of European case studies (Milan Malpensa, Zürich, Geneva, Frankfurt, München, Wien, Oslo), some correlation between the characteristics of rail connectivity to airports and the relative market share in airport accessibility may be found.

For instance, it occurs between the type of travelers and their preferences for mass public transport services, if the travel is long and made by nonresidents.

On the contrary, it is not possible to establish a univocal and solid correlation between the availability of a rail service and its times of access, costs, frequency, and comfort, although these factors are indeed crucial for rail competitiveness (Shujie and Xiuyun, 2012). The catchment area of an airport, in fact, is so variable in terms of preferences and travel needs that it does not seem possible to identify a model of optimal services in all contexts.

Some evidences, however appear, both in the literature and in actual practice.

- Rail is preferred when times of access are significantly lower than those achieved with other modes (road) and if price is aligned with the latter.
- The implementation or the reinforcement of a rail service to airports accessibility modifies passengers’ habits and parking facilities close to the airport.
- Passengers have a reduced preference for train changes.
- The market share to rail accessibility changes if rail services are differentiated in express, suburban. or long haul features.

The Management of Airports

To meet all the characteristics that an efficient air transport activity needs to serve demand and its territorial distribution, a crucial issue concerns its management. It has been pointed out that air transport is a vertical integrated activity, that is, an activity which needs at the same time to provide services (flights, managed by airline companies) and infrastructure (airports), the necessary but not sufficient condition to supply mobility services. In other words “vertical integration” means—in our case—that for the success of air transport in competition with other transport modes and for the sake of the economic returns of the different stakeholders, the management of the whole activity—separately for each of them—has to take into account both the infrastructural and the service

side. In fact, airport managers may not plan the development of the airport without considering what airlines will decide to establish their operational basis in the airport, how to allocate an adequate number of slots (Madas and Zografos, 2006) to the different airline companies. In turn, airline companies, will choose the airports that provide the services they need and whose catchment area is adequate for their desired market.

Focusing the attention on the management of infrastructure and avoiding to deal with nonspatial (i.e., “internal” to the airport) aspects (Brueckener, 2003), it is worth concentrating on the nature of airports and on some issues of their management that are often hinted to as “natural monopolies.”

Airports as “Natural Monopolies”

A natural monopoly is a monopolistic market firm, in which a firm is able to manage the entire supply of a service (or a good) at a lower cost with respect to any other firm. Usually, such a monopolistic form has a large size and benefits of very low average costs, due to economies of scale and growing scale returns. The larger is the production and the supply of the service, the lowest is the average cost of production and therefore its average cost and supply price of the service provided by the monopolistic firm. The potentially competing firms are not able to enter the market, as they are small and/or new comers: in fact, they, inevitably meet higher production costs. The natural monopoly occurs when the firm deals with an exclusive production factor (land, in the case of airports). The market is characterized by natural barriers that prevent other firms to enter that market. Despite its lower production costs, it is not obvious that the monopolistic firm will provide the service at a lower price: it will enable to sell the service at a high price, lowering it only when a new competing firm will try to enter the market. In our case, the firm (the airport) must manage large scale production “plants” serving a significant demand of services (provided by the airlines insisting on that airport). The vertically integrated firm must realize an infrastructure whose catchment area and accessibility are significant and efficient.

In these cases, an antitrust policy favorable to competition is inefficient, as it might cause the disappearance of the service and the growth of the market price. For this reason, public utility services (such as transport activities, air transport in particular) are often managed by public firms or by large private firms, which operate in a State regulated market to guarantee the presence on the territory of at least a firm, able to manage efficiently the plants (airport). The regulator may pretend that some service conditions are respected, such as the application of prices or tariffs at low level and the quality of the service (including a range of connections). To provide efficient air transport services in a particular area the State/Regulator may launch a tender to find a firm that—at those conditions—provides the services as a natural monopolist. In this way, competition is not warranted “in” the market, but “for” the market (Forsyth et al., 2004).

The final aim of the State is to cover the entire national territory with a plurality of airports (natural monopolies), trying to reduce at a minimum the overlapping of their catchment areas.

The natural monopolistic feature of an airport has been mentioned because of its spatial implications: in fact, the spatial subdivision of the airports market due to the accessibility to airports—and the consequent potential modal competition with rail—may deeply affect the economics and the management of air transport.

In general, airport managers will have to deal with all the spatial variables hinted to at the beginning of this note: that is, time and physical distances among origin and the destination of the flights served by the airport; level of development of the served destinations and of the area where the airport itself is located (Hu et al., 2015); the relevant catchment areas, modal, and intermodal accessibility. In addition, of course, to all the organizational on- and off-airport services provided to capture an increasing demand.

Finally, it is worth remembering that the horizons of airport management must include also possible agreements with the stakeholders of other modal infrastructure and services (railways, parking, car sharing). Such agreements help the demand—that air transport managers must interpret and anticipate—to identify its generalized cost of transport to evaluate its modal choice.

The “Generalized Cost” of Air Transport

The “generalized cost of transport” is a typical cost adopted in transport economics that measures not only the monetary cost faced by passengers and freight by using a particular transport service, but also the times implied in the door-to-door travel. Different modes present different generalized costs. In fact, if we take into consideration the different phases of mobility, we must measure the “first mile” phase (to reach a railway station, an airport, or even one’s car parking), the actual travel time, the “last mile” phase to reach the final destination. It is an everyday experience that, driving a personal car, the first and last mile phases imply an almost negligible components of “time costs,” but a longer time of travel. While, if one chooses to move by train, a longer time is needed to get to the station (and arrive with a sufficient advance to make sure to get the scheduled train), to a shorter time of actual travel and a further time from the station of arrival to the final destination. In the case of air transport, the advance with respect to the flight take off, in addition to the time to get the airport, is due to the check-in procedures, that change according to airports and type of flight (national, international, low cost, charter, and so on). On the contrary, the travel time is indeed shorter than by car or even by train. Finally, the “last mile” (exit) time will depend on the luggage delivery time and the distance of the arrival airport to the final destination. From these rough descriptions of the different segments of a travel door-to-door using different modes, it appears that the actual competition among modes is not only determined by the comparison of monetary costs, but it shows that is in fact the outcome of a choice is based on the generalized cost of transport, which is the sum/combination of money and time (and comfort, although difficult to estimate in economic terms).

It may be finally noted that income elasticity to the monetary cost and the value of time is not equal for all types of travelers: business men, tourists, students, and retired people show a different value of time and a different income elasticity to tariffs and therefore will have a different estimate of their generalized cost of transport.

Conclusions

Air transport, due to vertical integration of airports and airline services, has a profound impact on different scales of territory.

At the “local” scale—more or less corresponding to the catchment areas of airports—the impact has several features, essentially linked to the economic and social activities the air mobility implies and enables.

The location of firms is attracted by the existence and the size of an airport and by the connections that it allows. People living within the catchment area of the airport and willing to move by air are also subject to the nature of the airport (hub at point-to-point) and the connections it serves, both for business or for leisure purposes.

The impact at the local scale on passengers and freight mobility is of course stronger if efficient is the accessibility to the airport, made possible by the network of the feeding modes (road and rail). The generalized cost of air transport—in as much as it concerns both monetary and access time—is a relevant driving force in defining the scale impact.

At the wider, “global”, scale—domestic, continental, or intercontinental—effects are provided by the connection that airports allow (also in terms of flight frequency to the different destinations), and the efficiency of their operating management. Two examples are the provision of the relevant services to the different segment of demand and the planning of the slot framework for airline companies.

Introduction

This contribution focuses on travel behavior of young adults, defined here as the age group between 15 and 35. In most modern societies, this young adult period of life is the age bracket during which several important life changes take place. This usually includes leaving school, moving out from the parental home, attaining professional or academic education, getting one's first job and starting a family of one's own (Blumenberg et al., 2012). As for mobility, the teenage years in particular are also characterized by increasing mobility options which go along with maturing physical and cognitive skills (Chatterjee et al., 2018; ifmo, 2013; Kuhnimhof et al., 2019). This specifically includes the acquisition of driving licenses for motorcycles and cars. By the age of 18 most young adults around the globe have the right to obtain a driver's license, and in countries where economic conditions permit the majority makes use of this option (Kuhnimhof et al., 2012).

These consequential shifts in individual biographies and associated mobility options result in substantial travel pattern changes occurring during the young adult life stage. On average, in industrialized countries individual travel grows rapidly with increasing age between the ages of 15 and 35. In most cases this is primarily in the form of significant increases in driving (Chatterjee et al., 2018; Clark et al., 2016; Focas and Christidis, 2017).

Because of these fundamental shifts in life circumstances and individual travel, young adult mobility has for a long time been of special interest to researchers, planners and policy makers. In recent years, this topic has drawn additional attention because analysts identified changes in mobility trends among young adults in many industrialized countries. While there has been much heterogeneity across different places and different statistical indicators, the key findings included declines in license holding, car ownership and kilometers driven by young adults (ifmo, 2013; Kuhnimhof et al., 2012; Noble, 2005). These observations have led to the conjecture of declining car orientation among young adults (Grimal, 2018; Hjorthol, 2016; Le Vine et al., 2014).

These observations coincided with the rise of new mobility options and services such as car sharing, ride matching services or transport network companies whose most prominent representative is Uber (Marsden et al., 2018). The concurrence of the behavioral changes among young adults and the emergence of such new services has fueled expectations that a next generation of travelers would establish new mobility patterns with consequences specifically of reduced private car ownership and use (Delbosc and Ralph, 2017).

Against this background, this chapter's objective is to establish the status quo and recent trends in young adults' mobility. The focus of this contribution is on the situation of young adults in industrialized countries and much of the presented information applies to a broad range of high income countries. However, for illustration purposes, that is mostly for figures, this contribution uses data from Germany and England. (England is the focus of this analysis, rather than the United Kingdom as a whole, in respect of the use of England's National Travel Survey, which has no UK-wide equivalent.) These two countries represent the observations of wealthy European regions relatively well. Both countries lie between more car oriented industrialized countries such as the USA and less car oriented ones such as Japan (Ecola et al., 2014). Quantitative figures and specific facets of development vary across locales, however it is not the intent of this analysis to compare between the two countries in great depth, as some of the differences may be due to methodological differences in the German and English surveys.

It is also evident that the situation in emerging economies today is fundamentally different. The spatial and demographic factors linked with China's motorization, for instance, are markedly different than current trends in Europe and North America (Le Vine et al., 2018). Many aspects of future travel demand trends among young adults in emerging economies such as their private car orientation are subject to speculation, in part due to limited data availability. However, it appears reasonable to expect that young adults in emerging economies will in principle follow their wealthier counterparts in that mobility increases as they reach maturity and individual economic independence. Hence, this chapter also allows certain conclusions as to what can be expected regarding future mobility of adults in emerging economies.

This article is structured as follows: first, we present the socio-economic conditions of young adults and how these typically change as individuals transition through this stage of life; second, the article takes a closer look at the implications that this has on mobility options and travel behavior; third, we separate different dimensions of behavioral change that are important to understand aggregate changes in young adults' travel over time; finally, we discuss changes that have been observed with respect to travel of young adults in the last two decades and conclude the paper with final remarks and an outlook.

Young Adulthood: A Phase of Socio-Economic Transitions

To understand the fundamental changes in individual mobility which take place between the ages of 15 and 35 it is important to map relevant external framework conditions influencing travel behavior. A prototypical sequence of life events and stages, experienced by many but certainly not all individuals, involves completing school, moving out of the parents' household, pursuing higher education, getting a first job, moving in with a partner and starting a family. In each of these stages, a specific set of duties (e.g., school or work), desires (e.g., leisure activities or social needs), and possibilities (e.g., travel mode options or economic capability) shape the actual travel behavior. Hence, personal travel in each of these life stages differ and we observe substantial changes in average per-capita mobility indicators as individuals age and move through these different stages of life (Blumenberg et al., 2012; Delbosc and Currie, 2013b; Grimsrud and El-Geneidy, 2013; Oakil et al., 2016; Taylor et al., 2013; Waygood et al., 2020).

Figs. 1 and 2 exemplify the substantial changes in life circumstances taking place between the ages of 15 and 35 with regard to two influential dimensions of every day life, the family situation and the educational or professional situation. While teenagers under 18 live in households with children (because they are the children), **Fig. 1** shows a sharp drop as teenagers age into adulthood themselves. As a consequence, and with most having yet to have become parents themselves, the vast majority of those in their early twenties live in households without children. After this age, however, the proportion with children increases as these young adults start their own families. **Fig. 2** shows a similar sharp transition regarding the occupational status of young adults. While in the early twenties almost half of Germany's young adults pursue higher education, 80% have transitioned into the job market 10 years later. The situation in England is very similar, however, education and transitioning into the job market take place earlier.

Figs. 1 and 2 also illustrate changes that have occurred with respect to the composition of the population between 2002 and 2017 in Germany and England. Shifts regarding the occupational status of young adults (**Fig. 2**) are strongly influenced by economic conditions and specific national conditions of transitioning from school to higher education and economic activity. However, changes observed in **Fig. 1** specifically for Germany reflect a more global and long term trend: The age of family formation continues to shift towards higher ages (OECD, 2011). In many countries this goes along with a higher proportion of young adults pursuing higher education (which can be seen clearly in the 2002 vs. 2017 England data in **Fig. 2**), resulting in a later entry into the job market and age of settling into a stable career (ifmo, 2013). In short: the life stage of maturation is extending into later ages.

Figure 1 Proportion of population in households with children under 18 by age in 2002 and 2017 in Germany and England (Authors' own representation based on data from Bundesministerium für Verkehr- Bau- und Stadtentwicklung (BMVBS) (2010) and Bundesministerium für Verkehr und digitale Infrastruktur (BMVI) (2019)).

Figure 2 Proportion of population by occupation by age in Germany and England in 2002 and 2017 (Authors' own representation based on data from Bundesministerium für Verkehr- Bau-und Stadtentwicklung (BMVBS) (2010) and Bundesministerium für Verkehr und digitale Infrastruktur (BMVI) (2019)).

Advancing to a New Mobility Life Stage: More Options and More Travel

Between the ages of 15 and 35, the kilometers traveled per person per day increase by about 70% in both Germany and England. There are two main drivers for this development: First, there are new mobility options which specifically go along with driver license acquisition and access to cars. Second, there are stepwise changes from one life stage into the next which are often associated with increased mobility needs, such as commuting, and/or growing economic capabilities to travel via higher cost but more desirable modes (in terms of status or speed) (Oakil et al., 2016).

Figs. 3 and 4 illustrate differences in travel options and travel behavior among different young adult age groups in Germany and England in 2017. Here, the majority of young adults acquire a driving license by the age of 20 and from their mid-20s onward no less

Figure 3 License holding, car availability and kilometers per capita per day by age, Germany and England 2017 (Authors' own representation based on data from Bundesministerium für Verkehr und digitale Infrastruktur (BMVI) (2019)).

Figure 4 Trip based modal split by age, Germany 2017 (Authors own representation based on data from Bundesministerium für Verkehr und digitale Infrastruktur (BMVI) (2019)).

that two thirds of the population have access to a car within their household in both countries. Beyond the age of the early 20s, license holding and car access keep increasing, but at a much lower rate. The option to drive that a licence provides has an impact on both the total kilometers traveled as well as the modal split (Fig. 4). Hence, much of the growth in mobility during the young adult life stage can be attributed to the few years of age near 20 when acquisition of driving licenses is at its highest rate. There appears to be a somewhat sharper rate of change in Germany at this age with this change spread over a larger number of years among English youth.

From around age 20 onward, there are—on average—still increases of individual travel and modal shifts toward the car, but at a lower rate (particularly in Germany). During these years, significant life stage transitions and socio-economic change continue to take place, as seen above. But by that age the majority of young adults have already settled into a life style of substantial mobility which in many cases is heavily auto-oriented.

Intra- and Intergenerational Changes of Travel

While Figs. 3 and 4 reasonably illustrate the changes in mobility that occur as individuals age, they are actually imprecise representations of these processes. This is because in these snapshots (based on data from only the year 2017) different phenomena overlay, as the following example illustrates: The individuals in the first age bracket (15–17) were born almost two decades after those in the last age bracket (33–35). It is possible, that by the time 2017s teenagers reach 30 years of age, their travel behavior could be quite different from that of 2017s cohort of 30-year olds. They might transition differently through the different stages of young adults' mobility discussed previously. Thus, along with new constraints and opportunities such as from emerging technologies, they may eventually develop distinctive mobility patterns. This phenomenon is known amongst social scientists as a cohort effect.

These considerations lead to the differentiation of two important aspects of change regarding young adult mobility (Bell and Jones, 2013a; Bell and Jones, 2013b; Dargay et al., 2000; Ottmann, 2010):

- *Intra-generational* change of travel behavior describes the change in mobility that goes along with individual aging and transitioning from one life stage to the next. The sum of these individual transitions and the associated changes in life configurations and mobility patterns account for the average changes in travel behavior of a particular cohort or generation of young adults, for example, those born in the 1980s, as this cohort grows older.
- *Inter-generational* change of travel behavior describes the difference in mobility between members of different generations or cohorts, for example, those born in 1980 and those born in 2000, at similar ages or life stages. Inter-generational changes again can be broken down in two components delineating two areas of influential factors:
 - Inter-generational socio-economic shifts (e.g., those depicted in Figs. 1 and 2): Such socio-economic shifts affect how the population in a specific age bracket (e.g., ages 25–30) is composed of different groups, for example, proportion of those with or without children. As these subgroups will exhibit different mobility behavior from each other, socio-economic shifts contribute to different aggregate mobility indicators for different generations of young travelers.

- Intergenerational changes under socio-economic *ceteris paribus* conditions: Members of different year-of-birth cohorts or generations may exhibit different mobility behavior, even if socio-economic life situations resemble. For example, urban students at the age of twenty today may differ from 20-year-old urban students 10 years ago. Reasons for such intergenerational differences may be found in altered preferences or external factors such changes in the transport system.

Thorough analysis of young adults' mobility and its changes over time must take account of these two dimensions of change, as well as the two components of intergenerational change, in order to accurately identify the contributions of hypothesized explanations of changes.

Intergenerational Changes of Mobility Patterns Among Young Adults

Changes in young adults' travel behavior in industrialized countries which began in the late 1990s have drawn much research attention in the recent years. This mostly refers to intergenerational changes. After the turn of the millennium, researchers observed mobility patterns for the millennial generation, that is, those born in the early 1980s, which were unexpected. In short, earlier generations of young adults' exhibited increasingly car oriented mobility patterns relative to yet earlier generations. However, around the turn of the millennium these trends did not continue for the millennial generation. This raised much attention and hopes that the next generation of travelers would organically establish the more sustainable travel patterns that many in the transport and research policy communities seek to deliver (Blumenberg et al., 2012, 2013; Delbosc and Ralph, 2017; ifmo, 2013; Kuhnimhof et al., 2011).

Typical indicators evaluated in this context include license holding, car ownership, mode choice and vehicle kilometers traveled. However, the findings that contributed to this overall picture are extremely heterogeneous across different countries and travel indicators. In some places, license holding among young adults was found to decline, whereas in other places declines in car ownership and car use were found to be more pronounced (ifmo, 2013).

Not only the indicators differ but also the statistical sources for these indicators, which range from administrative databases (driving licence or vehicle registrations) to travel surveys and income/expenditure surveys. Despite this heterogeneity of data resources and findings, the decline of car orientation in young adults' travel in many industrialized countries seems to be sufficiently substantiated. However, the strength of this decline and which indicators are affected is debatable.

As for the reasons of the decline in car orientation, findings are similarly divergent. Many researchers attribute at least part of this trend to socio-economic developments (Chatterjee et al., 2018; Coogan et al., 2017; Delbosc and Currie, 2013a, 2013c). For instance, analyses for Germany and England indicated that between one third (England) and two thirds (Germany) of the decline in young adults' car ownership between 1998 and 2008 can be attributed to changes in income, place of residence (urban/rural), household composition and employment status (ifmo, 2013). There is also ample discussion of possible changes in preferences or psychological factors (Grimal, 2018; Hjorthol, 2016; Kuhnimhof et al., 2019). But the underlying figures are even less standardized across countries than the aforementioned travel indicators, and thus it has not been possible to credibly generalize.

Moreover, much of the research on young adult mobility that continues to frame today's discussion today was carried out in the years 2010–15. However, in some instances trends observed up to 2010 did not continue thereafter. For example, car registrations for young adults in Germany did not decline after 2010. Also in Germany, driver km per person per day has changed little after the 2000s (Kuhnimhof et al., 2019). In England, possible contributory factors that have been raised include rapid increases in motor insurance costs for young drivers, as well as changes to the driving licence acquisition process that have made "learning to drive" (i.e., developing the skills needed to pass the theory and on-road tests) a longer duration and more expensive process.

Concluding Remarks

Changes in young adults travel behavior in industrialized countries have drawn much attention in the past decade. While findings in the literature are not fully in agreement, there is clear indication that driving and the automobile are not as dominant for young adults' mobility as was the case prior to the turn of the millennium. Socio-economic shifts among young adults explain part but not all of this development. However, it is still uncertain which other factors have played a role.

Turning to the crucial question of what can be expected in coming years, it is also still unclear what recent developments will mean regarding the future travel habits of the millennials and successive cohorts as they age, start families and pursue professional careers. Persistence of mobility habits (e.g., modal preferences) acquired during the young adults' life stage is often conjectured. However, as of yet there is no reliable empirical evidence that the less car oriented mobility styles of the millennials carry on through later stages of life. However, it appears plausible that key life decisions made by young adults such as type of job, location of residence and work, starting a family etc. shape life configurations which in turn frame mobility in later stages of life. Hence, transport planners and policy makers should take advantage of the development among young adults, as it opens a window of opportunity to establish new and more sustainable travel patterns among future generations of travelers.

The observed changes in travel behavior for young adults should not be overrated, however. Research on young adults that has been carried out between 2010 and 2015, and is therefore not informed by the latest data, continue to be part of today's discussion,

both in the scholarly discourse as well as mass media, industry and the wider public. Developments after 2010 have yet to receive this same attention and in some instances “urban myths” unsupported by evidence persist in the public discussion. An example is the widespread belief in Germany that licensing rates among young adults are declining while the licensing register confirms that they are not (Böhm, 2015; NDR, 2019). The danger of a mis-informed public debate is the expectation that transport-related challenges will disappear as a new generation of travelers with more sustainable travel habits simply replaces more automobile-oriented predecessor generations.

However, there is no reason to ease policy efforts to guide personal travel in a more sustainable travel direction. The young adult life stage between 15 and 35 years of age continues to be characterized by life's most substantial changes and increases in travel, which nearly doubles during this 20-year period—mostly in the form of increased car use. The singular set of changes at this point in life has seen little change between successive generations of young adults. Hence, young adults' mobility will continue to be of special interest for policy makers and planners, as part of their efforts to ensure sustainable and efficient mobility patterns.

Introduction

The aviation sector is one of the crucial components that facilitates and boosts the world economy, moving passengers and cargo from different origins in countries all over the world to the final destinations. In doing so, it needs the complementarity from other transport modes as it is not possible to imagine a single pure air door-to-door trip, so air transport is in essence multimodal. For this reason, it produces a lot of spill-over effects in other transport modes as well as in other economic activities. [De Neufville and Odoni \(2013\)](#) contend that the aviation sector in the early 21st century is characterized by three important trends: (1) Long-term growth. An increase of 4% per year worldwide has implied that the traffic has been doubled about every 15–20 years. Thus, airports' expansions and new developments have been the norm in the sector. (2) Organizational change. The economic deregulation of the sector as well as the new open-skies agreements have been spread worldwide following the good results observed in the United States and the European Union. The privatization of airlines and airports has created new opportunities in the sector. (3) Technical change. This has been mainly observed in aircraft and air traffic control, but ICT is also expected to disrupt all industries and it is obvious that the aviation sector will not be an exception. The new technology will reshape the way some airport processes are performed, especially for safety, security screenings, and border controls. The new developments will increase airports' efficiency and airports need to be ready to this new era of rapid changes.

The increased demand for flights produces in many circumstances some delays, especially in those congested airports that suffer from lack of adequate capacity and operate near to the maximum capacity during some periods of the day, some weekdays, or certain peak moments. The Airports Council International (ACI) (2018) publishes the Annual World Airport Traffic Report (WATR), and finds that all regions experience a growth with a passenger and air cargo increase of 7.5% and 7.7% in the years 2017 and 2016, respectively. The aircraft traffic movements increased only by 3%. All in all, the airports worldwide accommodate 8277.7 million passengers, 118.6 million metric tons of cargo, and 95.8 million aircraft movements. The center of gravity of the sector shifts eastward as most of the world's fastest growing large airports are located in emerging markets. Sixteen of the fastest growing top 30 airports with over 15 million passengers are located in just two countries, China and India, and 13 airports out of the top 30 busiest passenger hubs are nowadays located in the Asia-Pacific region.

The International Air Transport Association (IATA) (2018) publishes the Annual Review and concludes that in 2017 airlines provided a record number of regular services to more than 20,000 city pairs. This figure doubles the number of existing connections reported in the year 1995. In the period 1995–2017, the flight tickets prices decreased by more than half in real (inflation-adjusted) terms. Some capacity shortages have been detected as airport construction was not able to keep pace with the increase in demand for aircraft movements. In 2017, more than 190 airports worldwide were slot constrained because they had insufficient capacity to meet demand at all hours of the day. The growth in air transport demand is directly transferred into major airport project developments, and the norm is that a number of massive investment projects for airport expansions or new construction are evolving conjointly at any time. Besides expansions and new constructions of airports, the capacity and congestion problems can also be tackled by innovation. According to [De Neufville and Odoni \(2013\)](#), the US aviation sector has led the major innovations affecting the airport planning and design worldwide. Some of the major innovations found by the authors are the following: economic deregulation; Southwest LCC model; US open skies policies; airline alliances; integrated air cargo services; transfer hubs; midfield concourses; automated people movers; and global positioning systems.

Another interesting trend observed in the last 30 years is that governments and public companies are participating less in the aviation sector. Thus, the market forces are nowadays more important than the highly regulated political context of the past, in which the outcomes were better explained by political and national interests. The aviation sector is converging very rapidly to a worldwide global industry. Privatization or corporatization in the airport industry can increase social welfare by the improvement of cost

efficiency, customer service, long-term investments, and innovation. The success of airport privatization or corporatization should be measured in terms of social welfare and not in isolated criteria like for example rates of return to governments or investors.

Similarly to the consolidation of the three global alliances, star, oneworld, and skyteam airports around the world have also explored whether the establishment of airport alliances, like for example, the Galaxy International Cargo Alliance (GICA), Aviation Handling Services (AHS), Pantares, and Aéroports de Paris (ADP)-Schiphol alliance will benefit the competitiveness of each individual airport. Technological spillovers and know-how transfer economic gains have been cited as the main motivations of this trend (Forsyth et al., 2010, 2011; Jiang et al., 2019). The results so far are not promising as most of the airport alliances have failed.

The new context is more oriented than ever to new commercial and economic challenges. Airport planners and designers are nowadays facing a variety of demands beyond the former petitions which were more oriented to standard norms. The business interests do not only include those from airlines but from different types of concessionaires. It is difficult to provide an exhaustive list of the main stakeholders involved in the airport network planning in a country but to cite some of them, it is possible to start with transport governmental policy makers, especially those working for the respective Aviation Administration Bodies, Airport Authorities or Aerospace National Agencies; consultants and practitioners whose professional careers are mainly developed in the field as, for example, CEOs of Airlines, Air Navigation Service Providers, Engineering and Architecture Firms, Oil Companies, Aircraft Manufacturers, Security-Planning-Environmental-Construction Companies, Parking-Airport Lounges-Retail, and Food and Beverages Development Solutions and Information and Communication Companies; and other CEOs of complementary and ancillary services, like for example, Air Traffic Control, Land Transport Companies, Railways, and Hotels. All these main stakeholders have different objectives, and this means that today airport planners need to think in terms of the social benefits taking into account multiple individual interests. De Neufville and Odoni (2013) summarize this by saying that the objectives of airport planners should consequently focus more on performance than on monuments with more low-cost and efficient terminals. Value for money, good service, and functionality are becoming the protagonists.

Airport planning guidance has been largely focused on individual airports, and less attention has been given to the interaction between airports at regional or national level, and to the interaction between the air transport and other transport modes at the time of developing intermodality. Nevertheless, Caves and Gosling (1999) highlight the need to analyze the context of the airport system when individual airport planning is considered. This need is supported by two main causes: (1) the existence of national or regional funding programs that aid airports' development; and (2) the emergence of multi airport city systems that exist in some important world metropolis. The interaction analysis is necessary because the catchment area of the airport developments in one jurisdiction might be extended to hundreds, if not thousands, of kilometers away. Thus, Caves and Gosling (1999) believe that the development of an integral planning of a system of airports, considering at least the main interactions between the airports and other transport modes, will result in a more efficient use of resources for a given provision of air transport services.

Morrel (2010) analyzes the European Commission's policy of encouraging airports to be intermodal hubs, highlighting that the successful cases will be based on something that airports and airlines have known for many years. The modal integration between air and other surface transport modes expands the airport's catchment area and enables airlines to compete in more origin-destination markets without providing additional air legs. High-speed rail (HSR) has been proven to be an excellent candidate for such development, especially as in the cases of Schiphol, Paris Charles de Gaulle, and Frankfurt International, where the HSR station is well connected with the airport and is fully integrated within the railways system. Thus, the passengers can travel from/to more destinations on the first or final leg of the trip without the requirement of making an additional connection. This is not achieved when there is a HSR direct connection between the airport and an important central station like, for example, the London Heathrow Express. The Commission's policy vision is aimed to move EU traffic from air to HSR, with alleged social benefits generated by the time savings, the better comfort provided by the HSR, the reduced congestion in the air approximation movements and the reduction in environmental costs.

The remainder of the chapter is organized as follows: "Literature Review" section reviews the previous studies highlighting mainly the integration between air and HSR. "Theoretical Models" section describes the analytical or theoretical models emphasizing mainly the modal integration between air and HSR. "Empirical Applications" section presents the main empirical applications on the topic. Finally, "Summary and Conclusions" section discusses the future research agenda and presents the main conclusions.

Literature Review

Jiang et al. (2017) highlight that the many of the airlines' hub-and-spoke networks could be used to complement air transport in the hub airports by HSR and other transport modes. Thus, one of the legs in which passengers are nowadays using the air transport will be substituted by HSR or other transport mode if a win-win situation is developed for airlines, HSR, terminals, and especially passengers. This type of integration has been mainly developed for HSR, conventional trains and interurban buses. It seems obvious that if HSR is a very competitive transport mode for trips of around 600 km, then these air legs can be substituted by HSR with an integrated service that can be viewed as a special type of "code sharing"—that is, two airlines cooperate to offer a hub-and-spoke operation with each offering one leg of a trip. Givoni and Banister (2006) analyze the possible relationships between air and HSR transport, finding three interesting states: competition, cooperation, and integration (see Table 1). The introduction of the HSR has given the chance to the railway to become a substitute to the aircraft on routes of about 600 km or a 1 h flight, and it has offered comparable or shorter travel times (from city center to city center). Therefore, transport modes have become substitutes for each

Table 1 Air and HSR relationship

	Market (city)	Relationships between air and rail		Rail link to airport?
		Modes	Operators	
Competition	City center (a) – City center (b)	Substitution	Substitution	No
Cooperation	Airport (a) – City center (a)	Complementary	Complementary	Yes
Integration	Airport (a) – city center (b)	Substitution/Complementary	Complementary	Yes

Source: Givoni and Banister (2006).

other since passengers can either use the aircraft or the railway. Considering that each transport mode is operated by a different operator, competition between them cannot be avoided.

Airports are located at the edge of cities and rail is usually used to access the airport. Therefore the two transport modes can be considered complementary since they both are chosen by users to travel from the origin to the destination and the service providers complement each other. This type of relationship defines cooperation since the two transport modes cooperate given that each mode is contributing and feeding traffic into the other network.

When railway infrastructure is provided at the airport, including the means for a fast and continuous transfer between the aircraft and the train, airlines can use railway services as spokes on their own services. While the airlines provide the service, the train companies can operate it and the two operators complement each other. The railway could serve destinations which were not served by the airline until now or could serve destinations already served. In the first case, the two transport modes work in a complementary way, that is, mode substitution does not exist, while in the second case transport mode substitution takes place and they are used in a complementary way (a flight and a railway journey are used in combination) and are substitutes (on one section either the aircraft or the train can be chosen).

As said, the integrated service should provide a win-win situation for the main stakeholders involved in such development. Jiang et al. (2017) find as the main driving forces of the cooperation the following: (1) Airlines win. Some short-haul flights are unprofitable and only provide value to the airline to maintain the network. Thus, some of the connecting trips can be substituted by HSR (Givoni and Banister, 2006); (2). Hub airports win. Some hub airports, especially in the EU, are very congested and intermodal cooperation can permit that some short-haul slots could be transferred to long-haul routes because passengers in the short-haul route are transported by HSR under this new integrated scenario (Givoni and Banister, 2006; Janic, 2011; Jiang and Zhang, 2014). (3) Society wins. Policy makers usually favor the intermodality because it is usually believed that network integration is more efficient than isolated transport networks as the integration permits to better exploit the network externalities. In addition, in short-haul routes, the substitution of air passengers with HSR passengers is environmentally beneficial (D'Alfonso et al., 2015, 2016). (4) Some foreign airlines win. Some foreign airlines do not have the freedom to enter in some domestic markets, but with the help of the integrated service, the airlines can make a detour and increase the market presence competing with other domestic airlines (Chiambaretto and Decker, 2012; Chiambaretto, 2015). As seen, there are many stakeholders involved, but, so far, airlines have been the more active agents of the integrated services, but it is true that policy makers, HSR operators, the hub airport and the passengers are also actively involved in such development.

Analytical models that analyze Air-HSR modal integration and change the focus from competition to cooperation started in 2010s (Socorro and Vicens, 2013; Jiang and Zhang, 2014; Avenali et al., 2018; Xia and Zhang, 2016, 2017; Jiang et al., 2017). In most of the cases, Air-HSR integration is studied throughout a very basic agreement and network features, in which the costs associated to the integrated terminal seem to come out of the blue. There are some exceptions, Avenali et al. (2018) consider the effects of the sunk costs of the integrated terminal, and Jiang et al. (2017) extend the previous papers considering two important features that were not sufficiently explored: (1) the basics of the network is extended because the HSR operator might cooperate with more than one airline; and (2) the type of modal integration is more heterogeneous, ranging from basic service that only considers a sort of protection agreement that covers major delays to more advanced integrated services with features like seamless tickets, dedicated carriage, coordinated scheduling, and baggage push. Nevertheless, dedicated carriage trains for the luggage are nor common, and there is an opportunity for other tertiary service providers that could take care of the O-D luggage traffic.

The Air-HSR modal integration phenomenon has emerged very intensively because of the existing interests of policy makers who have pushed toward the formation of some Air-HSR partnerships, especially in the EU. The empirical applications that deal with Air-HSR also started in 2010s but are less present in the international literature w.r.t. the theoretical ones (Román and Martín, 2014; Brida et al., 2017; Li and Sheng, 2016; Song et al., 2018). Moreover, it is odd to observe that the few empirical existing studies have not been used in the theoretical models to analyze the diversity of Air-HSR scenarios. The empirical applications have better grounds in the real world than the corresponding theoretical models. Thus, it is fair to suggest using the insights found in the empirical applications and to infer some proxies for the intervening parameters of the theoretical models.

Theoretical Models

Most of the international literature looks at transport mode alternatives in competition with each other proposing theoretical approaches to model this phenomenon. Not many are the contributions on the potential for their integration. [Givoni and Banister \(2006\)](#) argued that in the case of aircraft and HS train services the potential benefits from integration between modes and operators are greater than the benefits from competition. Indeed, the increase of the airport's capacity, through a railway station instead of a new runway, produces social-economic benefits at a lower environmental cost. Moreover, the presence of a railway station in an airport represents a step toward an integrated transportation system. Airlines use railway services as spokes in their network of services from a hub airport to complement and substitute for conventional air services. Railways play an important role in the future of air transport and the [Givoni and Banister's \(2006\)](#) recommendation was to extend the definition of air transport infrastructure in order to integrate the railways. This is fundamental in order to make policy makers thinking about the two transport modes as part of one transport network promoting airline and railway integration. Furthermore, it is necessary to guarantee adequate planning of railway services to and from airports. In order to provide direct, fast, and high-frequency services to many destinations from the airport, the airport itself should be a stop on a conventional railway main line and preferably also on a HSR line, with the result of having a terminal where all services can stop. This can be applied to large airports as well as to smaller ones, with some small modifications.

[Grimme \(2007\)](#) suggested that the decisive prerequisites of successful intermodal products were the availability of the comparable HSR journey time and the integration of airports into the HSR network. Moreover, he reported that very limited slots were freed for alternative use. [Chiambaretto and Decker \(2012\)](#) discussed some competitive issues associated with the AH intermodal agreements. The latter provide a number of potential advantages for airlines, rail operators, intermodal airports, and consumers of transportation services. These agreements involve a form of cooperation between airlines and operators that could, in principle, raise competition concerns. This is the case where agreements involve air and rail services that operate in parallel on a given route, and where the two services are potential substitute forms of transportation.

These contributions have demonstrated the advantages and disadvantages of air-railways integration services. However, they usually adopted a qualitative and descriptive approach and thus failed to quantitatively analyze the effects of the air-railways intermodality on the air transport markets.

[Socorro and Vicens \(2013\)](#) proposed a theoretical model to analyze the social and environmental impacts of airline and HSR integration in two different scenarios, that is, airports with capacity constraints and airports with low airline competition. They considered an economy composed of an oligopolistic sector and a competitive sector summarizing the rest of the economy. The theoretical model developed allows explaining formally why companies can benefit from air-rail integration. When mode substitution takes place due to integration, the companies that integrate can enjoy a higher market power. Moreover, if marginal costs are lower for the HSR, integration implies efficiency gains. It is also shown that integration is always profitable for the airline and for the HSR company when they have access to a new market due to integration. Moreover they showed that airline and HSR integration is more likely to be welfare enhancing if the airport is capacity-constrained. These results would justify, from a social point of view, airline and railway integration in airports that are highly congested.

Integration releases airport slots but the environmental question to promote integration is less straightforward given that more trips take place. In contrast, with no capacity constraints, integration does not necessarily imply a higher covered demand, and, in this case, mode substitution sets some trade-offs, that is, mode substitution is environmentally positive, but on the other hand, it eliminates competition in the market. They found also that in monopoly markets, the main impact of integration is to foster competition. When an airline and the HS train integrates, their combination results in an alternative way of traveling for passengers, thus removing the monopoly status of the airline that was already operating the market. Therefore, integration may introduce competition in markets where competition between airlines is low and particularly in those routes where the HS train is seen as a good substitute for the airline. In this case, integration would mean more competition and therefore lower prices, more variety for consumers, and higher social welfare.

[Jiang and Zhang \(2014\)](#) proposed a different analytical framework to address the welfare effects of air and HSR cooperation under hub airport constraint. They analyzed the economies of traffic density, and vertical differentiation between modes and heterogeneous passenger types. In their model, they assumed that the passenger demand function was specified as linear function. They found that such cooperation reduces traffic in markets where prior modal competition occurs but may increase traffic in other markets of the network. The cooperation improves welfare, independent of whether the hub capacity is constrained, as long as the modal substitutability in the overlapping markets is low. However, if the modal substitutability is high, then hub capacity plays an important role in assessing the welfare impact: if the hub airports are significantly capacity-constrained, the cooperation improves welfare; otherwise, it is likely welfare reducing.

Forecasting passenger demand for the intermodal service is important for stakeholders to evaluate the economic viability of the AH intermodal service. In practice, the passenger demand for such intermodal service is affected by various factors, such as connection time, the luggage through-handling service level, the integrated ticket price, and the competition from other travel modes. [Chiambaretto et al. \(2013\)](#) proposed a conjoint analysis to measure the willingness-to-pay (WTP) of passengers for using the AH intermodal service under different service levels. They showed the differences in the reservation price of passengers according to passengers' socioeconomic characteristics. [Zhi-Chun and Sheng \(2016\)](#) investigated the mode choice behavior of intercity passengers among air transport, HSR, and AH integration services. Stated preference surveys were employed and mode share models were estimated based on the collected data. The models developed were used to identify the key factors affecting users' mode choices and

to estimate the modal share of passenger travel demand for some intercity transportation markets. Sensitivity analysis was carried out as well with the objective of revealing the market potential of the AH integration service. It was then demonstrated that when the intercity travel distance exceeded a threshold, passengers became less sensitive to the connection time of the AH service. The most competitive haul distance for the AH service was between 1200 km and 1600 km and the en route travel time was the most important factor affecting the market share of the AH service.

Empirical Applications

Since the introduction of the first HSR line connecting the cities of Paris and Lyon, many empirical applications have analyzed the competition between HSR and air transport for distances no longer than 1000 km (see e.g., [Chang and Chang, 2004](#); [Román et al., 2007](#); [Jiménez and Betancor, 2012](#); [Dobruszkes et al., 2014](#); [Jung and Yoo, 2014](#); [D'Alfonso et al., 2015](#); [Zhao et al., 2018](#)). In these contributions, the focus was mainly on the identification of the different factors affecting the competition between these two transport modes which are considered substitutes rather than complementaries.

On the contrary, the empirical literature regarding the integration or cooperation between HSR and air transport is less rich, considering that most of these studies focused on passengers' perception of the main attributes that define the level of service of a given transport mode choice context, namely, transfer time, in-vehicle time, luggage transfer services, effort or transfer convenience, degree of fare integration considering different levels of risk split, and access/egress time. As for the area of application, most of the case studies have been conducted in Spain, the leading European country in developing the HSR network, and more recently in China, which has the world's largest HSR network.

The first paper dealing with the analysis of the mode choice behavior in the context of the integration of air and HSR is that of [Román and Martín \(2014\)](#). This work is based on a discrete choice experiment where passengers traveling between Gran Canaria (Canary Islands) and some peripheral cities in mainland Spain are confronted with the choice between the current air-air alternative and an integrated and hypothetical air-HSR option, where several scenarios of integration are considered. Results show that the different components of travel time, specially that used in making the connection between the two modes, as well as the fare integration are highly valued by passengers. In contrast, luggage integration resulted only significant for those who check in luggage and travel for leisure purposes. In a later work using the same data set, [Brida et al. \(2017\)](#) investigate how different market segments, obtained from a previous cluster analysis, have an influence in being more proactive to change to HSR for the second leg in the multimodal trips. Specifically, the results *"confirm the existence of groups of passengers differing in terms of their preferences for integrated multimodal services. A group of individuals appear to gather extra utility for the Air-HSR alternative. The likely factors characterizing this segment are travelling to the central business district as the final destination; higher attitude to work or have a meeting during the trip; interest to use mobile phone and WIFI during the trip; and younger age"* (p. 931).

[Li and Sheng \(2016\)](#) conducted a stated preference survey to passengers travelling in four city pairs located along the Beijing-Guangzhou corridor in China considering air, HSR, and the integrated Air-HSR as the different transport mode alternatives. Different choice models were estimated in order to identify the main drivers affecting mode choice and to determine the potential market share for integrated Air-HSR services in China. They found that haul distances between 1200 and 1600 km make the integrated Air-HSR alternative more competitive, and the in-vehicle travel time is the most important attribute affecting the market share for this option.

In a more recent work, [Song et al. \(2018\)](#) used last generation choice models to analyze how the variety-seeking attitude affects travelers' preferences in the context of Air-HSR intermodality in China. These models are based on the methodological framework proposed by [Ben-Akiva et al. \(2002\)](#) that integrates a latent variable model into the choice model, and are usually referred as integrated choice latent variable models (ICLV) or hybrid choice models. The data used in the analysis were obtained from a survey conducted at Shanghai Pudong International Airport, where travelers responded to different choice tasks and provided information about some attitudinal statements regarding the variety seeking. Thus, in the proposed ICLV, the utility of the different alternatives is explained not only by their characteristics but also by the latent construct of variety seeking which in turn explains the attitudinal statements. The main research findings *"suggest that variety-seeking has different impacts across modes, where variety seekers would be more likely to choose the newly-introduced integrated HSR-air option whereas variety avoiders have a higher propensity to choose car-air or traditional separate HSR-air alternative"* (p. 99).

Summary and Conclusions

[De Neufville and Odoni \(2013\)](#) contend that policy makers need to think strategically and to be flexible in developing tools for airport planning, management, and design. The economic and financial outputs associated with airport operations are nowadays more important than ever due to the observed trend of more commercial and private airports. Technical engineering capability is no longer enough to deliver an optimal social welfare for airports' planning, and a system approach that considers other transport modes and the mobility dynamics of the region and country is compulsory. The standards created in the past for some governments and international agencies are nowadays outdated, as they were mainly based on the planning of an isolated infrastructure without measuring adequately the important interactions that exist with other airports and transport modes. An airport is not independent; it is part of a worldwide transport networks system that is more or less interconnected. Airport planners need to study these

interactions, locally in its hinterland, domestically within the same country, and, internationally, analyzing each of the world regions. Conventional master plans have evolved into dynamic and flexible strategic plans.

De Neufville and Odoni (2013) also observe that many aspects of airport planning, design, and management are diverse across the world, regarding the level of innovation, the legal procedures or simply deep-grounded and traditional ways of doing. The cultural context usually imposes constraints on the main stakeholders involved in airport planning. The authors make the following list: (1) the role of central political power compared to that of the regions; (2) the permissible and desirable level of participation of private business; (3) the relative importance of technical experts and managers; (4) the criteria for excellent performance; and (5) the rights and capabilities of workers. They conclude saying that there is no single right answer—the concept of excellence depends on the context, and the “best practice” of one region may not be transferable to another. The authors find that, for example, in North America, the access to airports is mainly developed putting emphasis in the private cars and automobiles, so the provision of parking spaces is usually generous. Meanwhile, in the rest of the world, the emphasis is given to public ground transport, especially railways and HSTs.

Nowadays, an integrated approach between transport systems that facilitates intermodality such as rail and air services represents an important topic to discuss in the political agenda. It is considered a valid solution to the many transport problems that modern societies face (e.g., rising levels of accidents, emissions, and noise from transport) and plays an important role by enabling better mobility for travelers.

The sustained growth in demand for air travel has led airlines to rethink how they can maximize the effectiveness of their networks. One possibility is to improve the links with other transport modes. Intermodality at airports can involve a combination of: (1) accessibility to airports: local services between the airport and the neighboring city (e.g., via train); (2) complementary feeder services between the airport and the different parts of the surrounding region (mainly provided by buses, conventional trains, and more recently HSTs); (3) competing services between major city centers of neighboring regions; and alternative services that fully replace airline feeder services to airports (in general for those services of less than three hours’ train ride).

Partial or full substitution for air can be considered successful on short- or medium-haul journeys of up to 3 h provided by a HSTs (e.g., between Brussels and Paris). In this case, the train link can also be used to complement air travel, which can be used for the return journey or even at the beginning or end of an intercontinental flight, thus requiring that rail and air schedules, fares, and other transport facilities are carefully coordinated (www.atag.org).

Introduction

Airport management has become a major area of research as airports turned from an arm of government to businesses. Airports are part of the aviation infrastructure, but offer a variety of commercial services such as shops for travelers. They are regarded as strategically important for the economic development of regions. In the following we provide an overview of the most important issues of airport management. It is naturally selective and [Graham \(2018\)](#) offers a broader overview.

We start with the changes in privatization, regulation, and competition and how this affects the objectives of airport management. In the second section, we discuss airport costs and review the empirical evidence for natural monopoly. This is followed by two sections on pricing which discuss also the role of airport slots for managing scarce capacity and delays. In section five, we discuss forms of horizontal integration with their implications for airport strategy and competition policy. Thereafter, we give an overview of airport externalities. Among them noise is the most important. It is regarded as the most important obstacle for airport expansion in metropolitan areas. Before concluding the effects of changes in governance of the performance of airports are reviewed.

Governance and the Objectives of Airport Management

Airports are today governed by very different institutions than 30 years ago ([Forsyth et al. 2004, 2010](#); [Gillen, 2011](#); [Winston and de Rus, 2008](#)). The downstream market has been liberalized and airlines increasingly pressure airports for better services at lower costs. Ground handling, where many airports had a monopoly, has been partially opened up to competition. Likewise, with commercial services in which airports often have a superior position compared to other local suppliers, the Internet has also given the passengers more choices.

In 1986, UK government started privatizing the British Airport Authority. Privatization was seen as a role model for other countries, but many countries were reluctant to follow. There are substantial differences in the speed, the objectives and the form of privatization. The spectrum ranges from the model of full privatization, which has been adopted in Australia, New Zealand, Portugal, and the UK, to the model of partial privatization of airports with a government majority share, such as Copenhagen, Florence, and Rome to airports with a minority share such as Düsseldorf, Frankfurt, Hamburg, Vienna, Paris. The traditionally public airports have been corporatized, such as Schiphol, Dublin, and Milan. US airports, which are mostly managed at local level, are also public. Their contractual relationships with airlines and with the federal government make them distinct from public airports in Europe.

Privatization very often preserved market power and did not increase competition. This was the case with BAA, which was sold as one entity against the warnings of commentators such as [Starkie and Thompson \(1985\)](#). It was broken up 20 years later. Separation of the Paris Airports (ADP), the Spanish (AENA) and the Portuguese (ANA) airport system was never seriously discussed. When Bratislava Airport was to be privatized, the nearby Vienna airport would have taken over had it not been prevented by competition authorities. Moves toward privatization also failed, as in the case of Berlin Airport or Schiphol airports. In both cases, the public owners also increased the market power as neighboring regional airports were taken over or prevented from market entry. Privatization has generally not been used to increase competition. Cross ownership restrictions are to be found in Australia, where the airports are far away from each other, but not in Europe with a much higher airport density.

While airports see themselves as being in competition with other airports, airlines view them as natural monopolies. The intensity of competition is a controversial issue ([Maertens, 2012](#); [Starkie, 2001](#)). While many issues seem to be difficult to resolve,

there seems to be a consensus that the strength of competition should be assessed on a case by case basis by the competition authorities. In Europe, only the UK Civil Aviation Authority and Dutch Competition Authority did so. This resulted in the de-designation of the airports of Manchester and Stansted. Heathrow and Gatwick are still regulated, though Gatwick nowadays in a light-handed manner. Schiphol's market power was assessed in 2000 and 2009 as being persistent. There is evidence that, in Europe competition is growing, especially for small regional airports. Hubs face competition in the transfer market, but have a dominant position in the origin and destination market. Typically a few large airports in each country have persistent market power. The EU Directive on Airport Charges demands that airports above of 5 million passengers should be regulated. This was regarded as arbitrary, and policy should obviously be more careful to find out which airports should be subject to regulation.

The UK model of an independent regulator controlled by Parliament was also seen as a role model for airport regulation. It has been adopted in Australia and India, but faced resistance in the European Union. The EU Commission demanded that the regulator should be a part of the government which has no ownership share in the regulated airports. This model has been practised by some member states, such as Austria's. It has worked in some cases, but both airlines and airports fear that the other side can politically influence the regulator. Because of such fears, the regulatory agency should be independent from the government. Such a model has not been used much in continental Europe. In spite of all this, in many countries, for example Germany and Spain, the regulator is not independent at all and regulatory capture remains an issue.

Traditionally, airports have been subjected to cost-based regulation. UK-regulation adopted a hybrid price cap, which sets the price cap every 5 years on the regulated asset base (Forsyth et al., 2004). This model of incentive regulation became influential. In Australia, a price cap based was used in the first phase after privatization. Thereafter airports were monitored, a type of light handed regulation. Light-handed regulation does not formally regulate airports, but threatens airports with re-regulation in case of market power abuse. Its effectiveness depends on the credibility of such a threat—an issue which is currently controversial (Littlechild, 2018). A form of light-handed regulation has been used also in New Zealand. In Europe, Copenhagen and more recently Gatwick have been subject to light-handed regulation. UK price cap regulation has been adopted by some countries such as Italy, Portugal, Spain, France, and Hungary, but the incentives have been changed and very often lessened. A traffic risk sharing mechanism was included in the cap, which inversely relates changes in traffic to the level of regulated charges, so that the revenues are more or less stable and incentives weak.

Regulation of the UK airports determined the price cap by including the non-aeronautical commercial revenues (single till). This has been criticized as extending regulation indirectly into the contestable markets of commercial services. Australia opted for a price cap based on a dual till, and in Europe the airports of Hamburg and Malta were the first ones to adopt a dual till price cap. There is a growing trend towards dual till regulation, but unfortunately this is very often not combined with price caps, but with cost-based regulation (e.g., Germany). In such a case charges are relatively high and provide little any incentive for cost and allocative efficiency.

The changes and the diversity of the governance of airports lead to a number of interesting issues. What are airports maximizing? While fully private airports might behave in accordance with the profit maximizing model, it is not clear how the partially privatized airports, in particular those with a minority private share behave. Do they maximize internal rents for managers and employees? Do they try to maximize size and output? Do they try to maximize connectivity for the region or even for the nation? Do they cooperate with and even collude with the dominant airline? What role do private investors play? Are they bringing in entrepreneurial spirit and superior expertise, or are they merely financial investors in a low-risk monopolistic airports with stable rates of return? Are commercialized public airports much different from private or partially privatized airports? Do they take the risks and rewards of incentive regulation as their private counterparts? Many of these questions have not been well researched at all.

Airport Costs

Early research in the 1990s suggested that economies of scale run out about 3–5 million passengers. This would have implied that there were no structural barriers to entry so that competition could work. However, market entry did not occur in regions with excess demand. Recent research based on data from 1991 to 2008 concluded that economies of scale prevail up to 80 million so that most airports are natural monopolies (Martín and Voltes-Dorta, 2011). However, these studies should be taken with some skepticism as the cost and scarcity of land is difficult to capture, and studies estimate only the private costs of airports which do not reflect costs for the users in form of longer taxi times for aircraft or longer paths for passenger to reach the gate. Furthermore, airports are multi-product firms which mean that economies of scope are important, but there are hardly any studies on economies of scope.

Airport investment is not only long term and lumpy by its nature, but also relation specific. As the runway and the terminal cannot be redeployed, the value of these assets depends on how airlines use it. Airports and airlines enter into long run contractual relationships among which regulatory contracts are one form to avoid hold up problems and under investment. This implies that a large part of the fixed costs for airports are sunk, but also some of the airline costs at an airport have the character of sunk costs depending on whether the airline is operating a hub or a node at an airport (Biggar, 2012).

Pricing Aeronautical Services

For many years, until major airports became congested, there was a simple system of pricing aeronautical services, such runways. Aeronautical assets were sunk costs, and marginal and variable costs low. There was a cost recovery problem, and almost all airports

were subject to a weight-based formula, and airports would charge airlines according to the maximum take-off weight (MTOW) of the flight. This might be regarded as a form of charging what the market will bear, since larger aircraft would generate more revenue than smaller aircraft. This approach also has some desirable efficiency properties, since it is an approximation to Ramsey pricing, or pricing to minimize the reduction in traffic as a result of setting a price above marginal cost, which is close to zero, with most of the cost of runways and the like being sunk costs. There was no problem of rationing scarce capacity.

In time, excess demand developed at many airports, especially the major, busy airports. For many airports, land constraints and locational factors make it difficult to add capacity, especially in the short to medium term. This means that there is a problem of rationing scarce capacity. One option which has not been used much at all with airports has been that of peak load pricing, which has been used very extensively for other businesses (such as airlines) subject to peaks. There have been a few cases where airports have set minimum charges for use during the peaks, and this discourages small aircraft from using the airport in busy times. There have been two main approaches to rationing capacity at airports—congestion and queuing, and slots.

The congestion and queuing approach is used in the US extensively, though not in many other countries. It is a system of first come, first served. It means that queues develop, and sometimes the delays from these queues last for some hours. The main problem with a queuing system is that it is wasteful of time and other resources. This has been recognized for many years, though there has been little progress in finding a solution.

The alternative approach has been one of setting up a slot system at the airport (Czerny et al., 2008). In order to use the airport at a specified time, an airline needs to have a slot. These slots will be in short supply in busy periods, and if an airline is unable to obtain a slot for its preferred time, it will need to accept a less preferred time, or not use the airport. The key advantage is the slot system is that queuing time can be reduced, though not eliminated. A critical question is how the valuable slots are allocated. In most countries, this is done by “grandfathering”—if an airline has a slot, it keeps it, unless it is not using it. This may be administratively simple, but it has its drawbacks. In particular, it becomes difficult for new airlines to access the airport—low cost carriers have responded to this by flying to smaller, out-of-town airports and built up their businesses in this way. Airlines also trade slots through “grey” markets, and in the UK, open trading of slots is permitted and used (the current record for a slot pair at London Heathrow airport is \$US75m). More flexible administrative slot rules could improve capacity utilization. There have been several attempts to reform the slot system to allow secondary trading and auctions, but so far these attempts have failed. While airports favor reform, airlines, which receive the slot rent, oppose it.

The move toward privatization and deregulation of airports has meant that aeronautical pricing structures have become more varied. Airports with spare capacity are actively seeking new airlines and new routes, and to this end, they have been offering airlines discounts for new routes. In some cases, they have been offering (confidential) fixed price contracts which last for several years. Another trend has been the move to passenger-based pricing.

Another trend which has been emerging has been a change in the level of charges. It has been argued by competition authorities and airline lobby groups that the greater freedom in pricing has enabled the airports to increase the overall level of charges. In earlier days, airport charges were mainly cost based. Privatization and less strict regulation have given the airports the incentive and freedom to increase their charges. There is some evidence that charges are rising. There may be good reasons for this. Investment in land-constrained airports is costly, and unit costs have been rising. The level of airport charges is becoming a hotly debated issue around the world.

Non-Aeronautical Services

Over the last few decades, non-aeronautical services have become a much more important part of an airport’s product mix, sometimes over 50% of the total, though this trend seems to have moderated in recent years (Graham, 2018). Airports provide a whole range of services, some of which are only distantly related to their core business. These services may include ground handling, retail, car parking, and provision of office and other space. The moves toward privatization and commercialization provided a stimulus to retail, so much so that airports are sometimes described as “shopping malls with runways attached.”

One management decision which airports must take concerns the reliance on contracting out. Some airports rely heavily on contracting out of services, such that a major airport may only have a few hundred direct employees. Others, particularly in Europe, have chosen to go with direct provision of services in-house. For example, some airports in Europe have chosen to provide (labor intensive) ground handling services in-house. This has not always been popular with airlines, who would prefer their own handling or use of their own chosen contractor. In the EU, larger airports are now required to open up ground handling to competition (Forsyth et al., 2010).

Airport Integration by Alliances and Mergers

Traditionally airports were either operated as single entities or as part of national airport systems. This changed with airport privatization. Airport holding companies were created such as Macquarie Airports and airports like ADP, and Frankfurt and Amsterdam Schiphol bid successfully for international contracts. Furthermore, some airports, like ADP and Schiphol, formed alliances. Some industry analysts viewed this process as being similar to the integration process in the airline industry. However the analogy is misleading because airport consolidation is not driven by network economies. In most cases, airports integrate to transfer know how.

Airport ownership across continents was mainly driven by new investment opportunities. Alliances have had mixed success. There are a few cases in which airports tried to actively increase market power through horizontal integration, like in the case of Vienna and Bratislava which was prevented by the competition authorities. On the other hand, given the lack of any cost savings from integration, the economic rationale for not breaking up airport system like ADP, AENA, and ANA at the time of privatization remains weak (Forsyth et al., 2010).

Noise, Emissions, and Other Environmental Externalities

Airports are generators of significant environmental externalities, such as noise, local emissions and greenhouse gas emissions (Lijesen et al., 2010). Of these, noise has been the most problematic until recently. Airport noise has been very unpopular with local communities, who lobby hard to prevent airport expansion or new airports (and governments often choose to locate new airports away from urban areas). The perception of the noise problem does not seem to be reducing, even though aircraft are becoming quieter. Governments have imposed a range of measures to reduce the noise problem, including curfews, restrictions on noisy aircraft, noise budgets and noise pricing. The more blunt measures, such as curfews, are effective, though they can be costly in discouraging economic activity. More nuanced measures, such as noise taxes or prices, do not seem to be particularly effective. Local emissions of harmful gases present similar problems to noise, though they are less obvious or controversial.

The big growing issue is that of airport's contribution to greenhouse gas emissions. These come from the direct emissions of the airport's operation, and the indirect effect of facilitation of emissions from aircraft (made worse if queues to take-off are long). Airports can control their own emissions to some degree, for example, by using power from renewable sources—a number of airports are now claiming to be carbon free. In the EU, they use electricity which is subject to the Emissions Trading Scheme, which puts a price on emissions. The actual construction and expansion of airports can be quite carbon intensive, with their reliance on large amounts of concrete, which is a carbon intensive product.

The role of airports in facilitating air transport emissions is an issue which is developing. Governments are being pressured to limit the expansion of airports, and to stop new airports from going ahead. Such restrictions have not been very carefully analyzed, and it is not clear to what extent they will reduce overall emissions. For example, restrictions placed on one airport may mainly lead to passengers using other, not restricted, airports.

Airport Expansion

With demand for air transport growing rapidly in most markets, airports need to expand their capacity. With small investments, such as a new apron, terminal upgrade or air bridge, this typically does not cause any major problems. The ownership of the airport will determine the criteria for evaluation. A public airport might seek to assess the benefits and costs of expansion to the owner, the airlines and the passengers. A privately owned airport might concentrate on the profitability of the expansion.

With larger investments, such as a major new terminal or runway, it will not be simply up to the airport to do what it wants (ITF, 2014). Many larger airports are subject to regulation, and the regulator has a large say in whether the investment goes ahead. With very large investments, the government may become the decision maker.

Taking the regulation case first, the airport will need to get the approval of the regulator to make the investment, as BAA did when it was developing Terminal 5 at London's Heathrow Airport. The airport may make the proposal to make the investment, but then the regulator takes over. It will make an assessment of whether the investment is worthwhile and investigate funding. Quite possibly, the airport will need to increase charges to fund the investment, and it will need approval from the regulator to increase charges. The regulator will also monitor quality of service, to check that the airport is not downgrading quality.

Airports themselves will have even less of a say when very large investments are being considered, such as when the Third Runway at Heathrow and the new airport in Berlin were proposed. The investment became a major public policy issue, and a separate Commission was set up to investigate options for London's Airports. The investment involved access to land and land use, access roads and climate policy.

A key part of these investments concerns the choice of evaluation technique. The most commonly used are cost benefit analysis (CBA) and economic impact assessment (EIA).

CBA was designed to evaluate investments from a public policy perspective. The effects on all of the stakeholders—the airport, airlines, passengers and the local and wider communities are considered. Externalities such as noise, and increasingly, carbon emissions are estimated and costed. A related development has been that of computable general equilibrium modeling—this enables the decision maker to evaluate effects on the wider economy; such effects on GDP and employment, and measure the effects on income distribution and carbon emissions. The London Airports Commission used both of these techniques.

A more controversial technique is EIA. This has been used in several airport evaluations, such that for the Berlin Airport. It claims to measure the impacts on GDP and employment, amongst other variables. It has several deficiencies, including not taking account of crowding out and effects outside the project itself, ignoring price changes, and it effectively assumes that all resources are free. Not unexpectedly, it always predicts large positive impacts from projects. As a result, it is not to be trusted as a means of evaluating investments.

Performance of Airports

Analyzing the effects of privatization, regulation and competition on the performance has been demanding (Liebert and Niemeier, 2013). This is partly due to the lack of good data. Measuring capital and including land turns out to be challenging, and most studies use some more or less problematic proxies. Comparisons across continents are extremely difficult and prone to distortion. Very often airports are just compared within certain regions for which the quality of data could be controlled. Early studies did not isolate the effects from changes in ownership from changes in regulation and competition. Furthermore, studies just focused on cost efficiency leaving the question whether efficiency gains have been passed, via lower airport charges, to the airlines and passenger unanswered. All this reduces the number of studies to a few reliable studies.

According to these, privatization does improve cost efficiency but partial privatization does not. This makes the dominant form of privatization in Continental Europe problematic. Competition has the strongest effects on efficiency if the catchment areas overlap much. However, this is very often not the case, for geographical or policy reasons, so that regulation must set the incentives (Adler and Liebert, 2014). Generally incentive regulation is superior to cost-based regulation and a dual till price cap is better than a single till. However, there are many types of incentive regulation, including light-handed regulations, and very often the strength of incentives is lessened. As a result, the slow move from cost-based regulation to incentive regulation in Europe brought some efficiency gains (Adler et al., 2015). Many countries adhere to cost-based regulation, even for partially privatized airports. Here it is doubtful as to whether increased competition has changed the airport performance by much.

Summary

The literature on airport management shows that airport management can be improved in many countries. Governance is in particular important as many countries have not developed a coherent system of privatization, regulation and competition. Airport capacity has generally not been managed efficiently at the individual airport and the national level, causing too high cost of underutilized airports in rural regions and too high congestion costs at over utilized airports. Slot allocation has not been reformed. Environmental policy has been similar ineffective to internalize externalities. The expansion of capacity has often not been rigorously assessed and there are cases of white elephant projects as well as delayed welfare increasing projects. Airport management has turned into a complex policy problem offering a fascinating field of research for a political economy approach to airport management.

Introduction

A share of around 7.5% of airline operating costs is determined by user charges including airport charges (IATA, 2017). Compared to the share of aircraft fuel and oil costs, which is 22.5% (IATA, 2017), the role of airport charges seems relatively minor. Yet, airlines highlight the importance of regulatory controls for airport charges provided by the government (IATA, 2019). This can be understood given that the absolute value of the total airline payments to airports are substantive despite the fact that the importance of these payments relative to the total sum of operating costs seems minor. Governments are concerned about airport charges because they affect airline profits and air fares, thus, passenger surplus (Van Dender, 2007; Bilotkach et al., 2012).

The present article provides an overview over airport pricing and airport regulatory issues discussed in the aviation industry and in academic research. A major feature of this article is to use highly stylized economic environments to illustrate the most fundamental insights about airport businesses developed in aviation practice and research. The very fact that highly simplified and stylized models are used should, however, be considered as “a feature and not a bug” that helps to provide guidance and clarify fundamental economic relationships without distraction from potentially less relevant practical problems (Rodrik, 2015). For instance, the following discussion will concentrate on passenger businesses, and thus, abstract away from air cargo businesses because the main ideas presented in this article can easily be extended to air cargo businesses while concentrating on passenger traffic simplifies the language.

Airport Pricing of Infrastructure and Concession Businesses

The two-passenger example described in Table 1 is used to illustrate the airlines’ concerns about excessive airport pricing in the absence of regulatory controls provided by the government. Consider two passengers, A and B. The two passengers differ in their willingness to pay (WTP) for a flight. Passenger A’s WTP for a flight is 10, while passenger B’s WTP is only 3. Consider a situation where the airport can control how much they can earn from passengers and also how much passengers pay for their flights, which can be described as a situation where airports have and exercise market power (airlines are left out of this consideration because they are not essential when it comes to demonstrate the possibly detrimental effects of airport market power). The airport chooses between prices 10 and 3. If the airport charges a price of 10, then only passenger A will fly, while a price of 3 would ensure a demand of both passengers A and B. Consider airport operating costs of 2 per passenger. In this case the airport profit would be equal to 8 if a price of 10 is charged, which is high relative to the profit of 2 ($= 2 \times 3 - 2 \times 2$) that would be realized when a price of 3 is charged. Thus, if the airport pursues profit maximization, it would charge a price of 10 (not 3).

A price of 10 is excessive from the viewpoint of a government that cares about airport profits and also the surplus of passengers. To see this, note that the surplus of passengers is zero in the case of a price of 10 because passenger A pays a price that is exactly equal to her WTP while passenger B does not even fly. A price of 3 or less would secure a surplus of 7 or more to passenger A and ensure that passenger B flies. If the price is equal to 3, the sum of profits and passenger surplus is given by 9, which is higher than the corresponding sum if a price of 10 is charged. The price could be further reduced to 2. If a price of 2 is chosen, then the airport profit would be zero and the passengers’ aggregate surplus would be even further increased and given by 9. Many airports in the world follow such a not-for-profit approach. Airports in Canada serve as examples (Tretheway, 2006). Altogether, this illustrates the potentially conflicting goals of profit-maximizing airports and policy makers.

Table 1 Two-passenger example in the absence of non-aeronautical businesses

	<i>Passenger A</i>	<i>Passenger B</i>
Willingness to Pay (WTP)	10	3

Table 2 Two-passenger example in the presence of non-aeronautical businesses and myopic passengers

	<i>Passenger A</i>	<i>Passenger B</i>
WTP	10	3
Concession profit	5	10

Myopic Passengers

Until now, the framework considered airports as a firm that offers a single product or service. In the year 2017, 40% of airport revenues came from non-aeronautical revenue sources, which included revenues from the supply of retail concessions (30%), car parking (20%), property and real estate (15%) as well as other sources (ACI, 2019). Because a large share of airport revenues came from non-aeronautical businesses, the question arises how they affect the infrastructure pricing of a profit-maximizing airport.

Zhang and Zhang (1997, 2003, 2010) were among the first to study the effect of non-aeronautical airport businesses on aeronautical prices. Their research highlighted the role of revenues from concessions for airport cost recovery from the viewpoint of public and welfare-maximizing airports. Starkie (2001), on the other hand, highlighted the relevance of non-aeronautical businesses for profit-maximizing airports. He mentioned that the presence of non-aeronautical airport businesses would make formal price controls of aeronautical airport charges unnecessary. The example in Table 2 is used to illustrate his line of reasoning. In this example, passenger A travels if the ticket price does not exceed 10; however, in the case of flying, passenger A will make use of non-aeronautical airport services which generates an additional airport profit of 5. Passenger B travels if the ticket price does not exceed 3; however, in the case of flying, passenger B will generate an additional airport profit of 10. The fact that, in this example, the WTP for the flight is the same as in Table 1 is used to capture the notion of myopic passengers who do not anticipate a surplus from the consumption of non-aeronautical airport supplies when they decide upon traveling.

The scenario described in Table 2 implies a profit-maximizing price for aeronautical supplies equal to 3. Reducing the price for aeronautical businesses pays off for the profit-maximizing airport because it encourages passenger B to travel and passenger B generates a relatively high profit from non-aeronautical businesses. More specifically, the reduction of the aeronautical charge reduces the aeronautical revenue by 7 and increases the non-aeronautical revenue by 5 from passenger A, while it increases the aeronautical profit by 1 and non-aeronautical profit by 10 from passenger B. This scenario, thus, demonstrates that profit-maximizing airports may reduce the aeronautical charge in order to boost passenger demand and non-aeronautical businesses. This result has also been highlighted by Morrison (2009), Czerny (2013), Gillen and Mantin (2014), and Kidokoro et al. (2016) among others.

Foresighted Passengers

A crucial assumption of the example in Table 2 is whether passengers really do not anticipate the consumption of non-aeronautical airport services in the moment of booking a flight. Consider, for example, car rental and car parking services. Passengers and especially business passengers are likely to be aware of the need to use car rental or car parking services as part of their trips (Czerny et al., 2016b). It therefore seems important to capture the case of foresighted passengers. Czerny (2006) showed that the result of the above-mentioned example, profit-maximizing airports reducing the aeronautical charges to boost concession businesses, can be reversed in the case of foresighted passengers. He shows that, with foresighted passengers, profit-maximizing airports may develop concession contracts designed to reduce the charges for non-aeronautical supplies to boost their aeronautical businesses (Czerny, 2006; Czerny and Lindsey, 2014; Flores-Fillol et al., 2017).

The example in Table 3 illustrates the case of foresighted passengers. In the absence of airport car-rental supplies, the passengers' WTP are equal to the ones mentioned in Table 1. Car rentals do, however, change the WTP of passengers if airport car rental supplies

Table 3 Two-passenger example in the presence of non-aeronautical businesses and foresighted passengers

	<i>Passenger A</i>	<i>Passenger B</i>
WTP without car rent	10	3
WTP with car rent	9	9

are used. Consider the case of passenger A. The use of car rentals reduces this passenger's WTP. The reason may be that passenger A does not possess a driving license and, therefore, would have to pay a car parking fee, if he would have to rent the car. Or, passenger A simply enjoys being picked up by family members and friends. Renting a car would eliminate the joy of being picked up and therefore reduce the overall WTP for the trip. Passenger B is different. Passenger B may represent a business traveler, who needs a car to reduce the travel time needed to reach the final destination and for whom saving travel time is important. Passenger B represents passengers whose WTP for the whole trip would be significantly increased by the use of airport car-rental services.

Consider zero costs of car rental supplies. In this case, the profit-maximizing airport would charge a price equal to -1 for car rental services and a price of 10 for aeronautical services. This means that the airport maximizes profit by providing car rental services below costs to boost passenger demand and charge a high price for aeronautical services. The airport could offer take-it-or-leave-it contracts to concessionaires to impose the desired prices for non-aeronautical supplies. Passenger surplus is zero in this situation, which means that the profit-maximizing prices help the airport to internalize the entire surplus in the market in this specific example. Interestingly, passenger surplus could be raised in this example by imposing a minimum price, that is, a price floor for car rental services. For instance, policy makers could impose a lower limit (not an upper limit) on car rental prices. Consider a lower price limit of zero, which is just enough to ensure to avoid producing a profit loss from car rental supplies. In this situation, the profit-maximizing aeronautical charge is equal to 9, which leaves a passenger surplus of 1 to passenger A.^a

Airport Ancillary and City-Center Supplies

Airports often relate their charges for non-aeronautical ancillary supplies to city-center prices (Czerny and Zhang, 2018). For instance, airports in Atlanta and Vancouver impose an upper limit on prices for ancillary supplies based on the corresponding city-center prices. Hong Kong airport launched an "Urban Price Protection" scheme in 2004, which requires airport retailers and restaurant operators to charge prices that do not exceed the city-center prices. Capturing the rivalry between airport ancillary and city-center supplies, Czerny and Zhang (2018) derived an independence result, which states that, under certain conditions, the assessment of equilibrium prices charged by a profit-maximizing airport and profit-maximizing city-center prices are independent of whether passengers are myopic or foresighted. This is a surprising result given that profit-maximizing airport charges may be low to boost non-aeronautical businesses when passengers are myopic while the opposite could be true in the case of foresighted passengers.

Bracaglia et al. (2014) highlighted that passengers may be more foresighted today than in the past because airports are increasingly involved in e-commerce activities, which allows passengers to easily gain a more complete picture of all travel expenses including, for example, car rental, and car parking payments. That airports may induce congestion to increase the passengers' time spend at the airport and boost non-aeronautical airport businesses has been found by D'Alfonso et al. (2013) and Wan et al. (2015). Most airport studies abstract away from the possibility that people travel to the airport only to demand non-aeronautical airport supplies and not for flight reasons, which is a feature covered by D'Alfonso et al. (2017). Survey papers reviewing the research related to aeronautical and non-aeronautical airport services are provided by Zhang and Czerny (2012) and D'Alfonso and Bracaglia (2017).

Cost-Based Versus Incentive Regulation

The above analysis of profit-maximizing airport charges for aeronautical and non-aeronautical supplies reveals that profit-maximizing aeronautical charges can be excessive from the viewpoint of policy makers despite the important role of non-aeronautical businesses for airports. The present section describes cost-based and incentive-based forms of regulating airport aeronautical charges and their effects on profit-maximizing airport aeronautical charges and airport investments. The consideration of non-aeronautical businesses is not essential to demonstrate the effects of these two regulatory regimes and will therefore be postponed to the subsequent section.

Pricing

Cost-based forms of regulation have in common that they relate revenues with costs in the sense that firms can increase the revenue in the case of a cost increase (Czerny et al., 2016a). Cost-based regulation is, for example, popular in the United States where airports strictly operate as public enterprises (Bilotkach et al., 2012). One way of creating such a regulatory environment is to impose an upper limit on the Return on Investment (ROI), which may be defined as the fraction of profit over investment costs:

$$\text{ROI} = \frac{\text{Profit}}{\text{Investment costs}} \quad (1)$$

Table 4 is used to illustrate the functioning of cost-based regulation and its possible impacts on the airport's regulated prices. Consider an airport that can choose prices of 25, 10, and 5 for aeronautical services. The passenger demand (pax) is equal to 3 when

^aThat price floors on ancillary supplies can increase the surplus of consumers has recently been highlighted by Gomes and Tirole (2018).

Table 4 Cost-based regulation when investments are given

Price	Pax	Revenue	Investment	Profit	ROI
25	3	75	50	25	50%
10	10	100	50	50	100%
5	15	75	50	25	50%

the price is equal to 25, 10 when the price is equal to 10, and 15 when the price is equal to 3. Investments are given by 50. The ROI is maximized when a price of 10 is charged, which leads to a revenue of 100, a profit of 50, and an ROI value of 100%.

The regulator may be unsatisfied with the price of 10 because passenger numbers could be substantially increased by a price reduction from 10 to 5 while maintaining airport cost recovery. The regulator therefore tightens regulation by imposing an upper limit of 50% on the airport's ROI. The airport's response to this policy change is, however, ambiguous in the sense that both a price reduction from 10 to 5 and a price increase from 10 to 15 satisfy the tightened regulatory constraint. This means that there is a risk that the tightened regulation may actually increase and not reduce the price, which is a highly undesired outcome from the policy perspective because this would drastically reduce the passenger number from 10 to 3 instead of increasing the passenger number from 10 to 15.

The ambiguity arises from the fact that the cost-based regulation implicitly imposes a limit on revenues and therefore essentially functions as a revenue-cap regulation; but, revenue is the product of the price and passenger number and therefore the same revenue can be achieved with a low price and high number of passengers and a high price and a low number of passengers. That revenue caps can increase rather than decrease prices has been highlighted by [Crew and Kleindorfer \(1996\)](#).

A simple way to resolve this ambiguity regarding regulated prices is to directly(!) regulate prices instead of ROI (and revenue). An upper limit on prices equal to 5, called price-cap, would ensure that the airport charges a price of 5 rather than 10 or even 15.

Investments

Cost-based regulatory practices can be considered as "traditional" ([Bilotkach et al., 2012](#)), while there has been a gradual trend toward price-cap regulatory regimes in Europe, India, and elsewhere ([Adler et al., 2015](#)). The reason is that price-cap regulatory regimes provide strong incentives for cutting costs relative to cost-based regulation; therefore, price-cap regulation is also called *incentive regulation*.

The example provided in [Table 5](#) is used to illustrate the role of regulatory regimes in the form of cost-based and incentive regulations for investments. It shows passenger numbers, revenues, profits, and ROIs for investments of 50 and 67. Prices and passenger numbers, thus, also revenues are independent of whether investments are equal to 50 or 67. This captures the scenarios where the additional investments of 17 (= 67–50) are *absolutely unnecessary* in the sense that they do not affect capacity, service quality, and passenger number. Expensive architectural designs of buildings or construction materials perhaps appreciated by experts but not necessarily by passengers in general may serve as examples.

Would airports invest the additional amount of 17? This seems a ridiculous strategy because the investment is absolutely unnecessary by construction. A profit-maximizing airport that is unregulated certainly would not do the investment because it increases costs but leaves revenues unchanged, thus, reducing profit defined by the difference between revenues and costs. The picture changes under cost-based regulation.

If the airport's ROI is limited from above and investments are given, it can reduce or increase the price to satisfy the regulatory constraint. The resulting profit would be equal to 25. If investments are determined by the airport, the airport may leave the price unchanged and equal to 10 and respond to the tightening of the ROI requirements by spending the amount of 67 for investments. This is an alternative policy that satisfies the tightened regulatory constraint of an ROI that does not exceed 50%. Increasing the investment is in fact the better strategy for the profit-maximizing airport because it leads to a profit of 33 which is higher than 25. This outcome is a disaster from the policy viewpoint because prices are unchanged by the tightened policy and resources are wasted.

One may wonder whether the outcome where regulated firms waste resources to charge higher prices is realistic because regulators should intervene in the case of unjustified costs and not include them into the "regulatory asset base" used to evaluate regulated prices. The problem here is information asymmetry because regulators are less well informed about industry needs and therefore can have difficulties in assessing the economic value of investment strategies. Price-cap or incentive regulation is used as

Table 5 Cost-based regulation when investments are chosen by the airport

Investment	Price	Pax	Revenue	Profit	ROI
50/67	25	3	75	25/8	50%/14%
50/67	10	10	100	50/33	100%/49%
50/67	5	15	75	25/8	50%/14%

a device that should help deal with information asymmetry by reducing the firms' incentives to waste resources (Beesley and Littlechild, 1989). For instance, consider a price cap of 5. In this case, the airport revenue will be 75 and independent of investments. The result is that the airport has no incentive to waste resources and invest in unnecessary assets. That a move from cost-based to incentive regulation can indeed improve productive efficiency in airport practice has been confirmed by Adler et al. (2015).

Clearly not all investments are unnecessary because investments are needed to, for example, improve service quality. The advantage of cost-based regulation is that it creates conditions that support investments in service quality, while incentive regulation provides strong incentives to cut costs by reducing service quality (Oum et al., 2004; Czerny and Forsyth, 2008; Yang and Zhang, 2012). This problematic feature of incentive regulation will be discussed in more detail in the subsequent section.

Single-Till Versus Dual-Till Regulation

The previous section concentrated on the regulation of aeronautical charges in the absence of non-aeronautical profits. How to deal with profits from non-aeronautical airport businesses is a big question in airport regulation (Lu and Pagliari, 2004). There are two main approaches called single-till and dual-till regulations. With single-till regulation, the profits derived from airport concession services are used to cover the airport infrastructure cost for, for example, runway construction, while the airport is supposed to cover airport infrastructure costs entirely by aeronautical revenues with dual-till regulation (Czerny et al., 2016a).

The functioning of single-till and dual-till regulation is illustrated based on its application to incentive regulation. Under single-till regulation, the price-cap may be written as:

$$\text{Single-till aeronautical charge} = \frac{\text{Investment costs} - \text{Non-aeronautical profit}}{\text{Passenger numbers}} \quad (2)$$

The right-hand side displays the fraction of the difference between investment costs and non-aeronautical profits over passenger numbers. This formula ensures airport cost recovery where a part of the costs of infrastructure investments is covered by the profit generated by non-aeronautical businesses. One advantage of the single-till approach is that it does not require attributing investment costs to aeronautical and non-aeronautical airport businesses, which is arbitrary to a large extent. This is different in the case of dual-till regulation because this regulation regime absolutely requires attributing investment costs to aeronautical and non-aeronautical businesses. Under dual-till regulation, the price-cap may be written as:

$$\text{Dual-till aeronautical charge} = \frac{\text{Infrastructure investment costs}}{\text{Passenger numbers}} \quad (3)$$

Thus, dual-till regulation requires separation of investment costs in investment costs for aeronautical and non-aeronautical businesses. The dual-till price cap is then chosen such that the aeronautical revenues are sufficiently high to cover infrastructure costs. Typically, this means that the single-till price cap is smaller than the dual-till price cap (Kratzsch and Sieg, 2011).

With foresighted passengers, airports can partly compensate the tougher price cap imposed by single-till relative to dual-till regulation by an increase in prices for non-aeronautical supplies (Czerny and Zhang, 2018). Consider the passenger example in Table 3 for illustration. If the dual-till price cap for aeronautical prices is equal to 10 under dual-till regulation, while it is equal to 8 under single-till regulation. In this scenario, the profit-maximizing car rental price equals -1 in the case of dual-till regulation (the price-cap constraint is non-binding in the sense that the profit-maximizing aeronautical charge is independent of the presence of airport regulation), while the profit-maximizing car rental price is given by 2 under single-till regulation (where the price-cap constraint is strictly binding in the sense that the profit-maximizing aeronautical charge is strictly higher in the absence of regulation).

Table 6 illustrates how dual-till regulation can stimulate investments and increase the incentives to improve service quality relative to single-till regulation. The first column shows that the airport can choose between investing 50 or 100 where the higher investment of 100 relative to the lower investment of 50 increases passenger numbers by 5, which is independent of the aeronautical charge in this example. If the aeronautical charge is equal to 25, then the airport profit increases from 25 to 100, that is, by 75. This means that aeronautical charge is so high that the increase in passenger numbers boosts revenue to an extent that makes it easy to cover the higher investment costs. If the aeronautical charge is equal to 10, then the airport profit remains constant and is equal to 50 independent of whether the investment is equal to 50 or 100. This is because the higher service quality boosts revenues to an extent that is just high enough to cover the increase in investment costs. If the aeronautical charge is equal

Table 6 Single-till versus dual-till and service quality

Investment	Aeronautical charge	Pax	Revenue	Profit	ROI
50/100	25	3/8	75/200	25/100	50%/100%
50/100	10	10/15	100/150	50/50	100%/50%
50/100	5	15/20	75/100	25/0	50%/0%

to 5, then the additional investment in service quality reduces airport profit to zero because the revenue increase is too small to cover the higher investment costs.

Altogether, this illustrates how a relaxed price constraint under dual-till regulation can increase the incentives to invest in service quality relative to single-till regulation (Oum et al., 2004; Yang and Fu, 2015). In the specific scenarios discussed here, this is because dual-till regulation may lead to a price cap of 10 or 25 while single-till regulation may lead to a price cap of 5. In these scenarios only dual-till regulation could ensure that the regulated firm will invest in service quality. This further illustrates how incentive regulation can provide strong incentives to cut costs even when this leads to poor service quality, which is especially true under single-till regulation. The result is further in line with the airports' view that dual-till regulations can be associated with more innovations in commercial airport businesses relative to single-till regulation (ACI, 2017). Yang and Zhang (2011) highlighted how dual-till regulation can more effectively manage airport congestion in the absence of airport slot limitations because the higher prices under dual-till relative to single-till regulations reduce airport traffic, thus, congestion.

Conclusions

The discussion in this chapter illustrated that airport regulations can take the form of cost-based, incentive, single-till, and dual-till regulations. The discussion further illustrated that no regulatory regime can solve all pricing and investment problems. Policy makers rather have to choose whether they would like to maintain, for example, a closer control of airport aeronautical charges, which may favor the use of incentive and single-till regulations, or provide an environment good for investments and service quality, which may favor the use of cost-based and dual-till regulations. Policy makers may even reject such forms of economic regulation of airport aeronautical charges to avoid regulatory interferences in airport decisions or because of the presence of airport competition. Examples are airports in Australia, New Zealand, and the United Kingdom. In Australia and New Zealand, the prices and service quality of all major airports are subject to light-hand regulation involving the monitoring of airport behaviors but not directly regulations (Forsyth, 2004, 2008; Yang and Fu, 2015). Airports in the London area of the United Kingdom are freed from regulation because of airport competition and because long-term contracts between airports and airlines are considered an effective tool for airport control (Czerny et al., 2016a).

Introduction

Since the turn of the 21st century, the growth in the air transport industry worldwide has been, by all means, impressive. Considering unique commercial city-pair connections, the sector nearly doubled, from approximately 11,000 routes in operation in 2000, to almost 20,000 in the year 2017 (IATA, 2018). As a result, there is an estimated daily average of more than 100,000 commercial passenger flights (IATA, 2018). These figures evidence an ongoing trend in the expansion of services in this industry.

While these numbers show considerable growth in the aviation sector, the establishment of services in unexploited markets continues to represent a significant challenge for airlines. Trial-and-error approaches, with new scheduled services being added according to their ability to have access to capital and assets, may prove to be risky, from both financial as well as reputational perspectives. The establishment of new routes require significant marketing investments to promote them, including the main competitive advantages offered by the new service offered (e.g., frequency, aircraft type, price, etc.).

In this chapter, we discuss two concepts closely related to these ideas, namely the processes of air route planning (ARP) and air route development (ARD). ARP, an activity usually done internally by airlines, is defined as the process of identifying the most efficient way of meeting the demand of a given route by providing adequate flight service. Attributes related to ARP include the number of seats offered on a route, the frequency of flights, the number of connections, the price, and the targeted level of comfort. In contrast, ARD refers to the combined industry effort to make a given route viable, and this is done through the engagement of several aviation and tourism stakeholders.

This chapter is organized as follows. In Section Air Route Planning, ARP is the focus, with a discussion on the determinants from the perspective of demand and supply. In Section Air Route Development, we emphasize the ARD process, presenting the objectives and the roles of the various stakeholders, predominantly airports, and destination management organizations (DMOs). Lastly, Section The Steps of the ARP and ARD Processes and their Integration concludes by bringing together the steps taken by airlines during ARP as well as by the remaining air transportation stakeholders during ARD, highlighting the interfaces between these two processes.

Air Route Planning (ARP)

Demand-Driven Factors

The most critical condition to be met for the establishment and maintenance of route operations is the need for potential passengers to travel between two places. Hence, an understanding of the determinants of air transportation passengers is paramount, and these can be divided into two main groups—geo-economic and airline service-related determinants (Wang and Song, 2010). Geo-economic factors, on one hand, distinguish themselves as they fall outside of the control of airlines. These include characteristics such as level of income, size of the population and demographic factors of the origin and destination regions, the distance between these points, the competition with secondary airports in the surrounding area, the existence/price of alternative transportation modes, the climate of both regions and their seasonality. In addition, macro-economic variables

Air Route Demand**Geo-economic factors**

- Income
- Population
- Demographics
- Distance
- Competing airports
- Price and existence of alternative modes
- Climate
- Seasonality
- Foreign trade
- Exchange rates

Service-related factors

- Level of comfort of the aircraft
- Aircraft capacity
- Aircraft range
- In-flight amenities
- Frequent flyer programs
- Safety record
- Airfares
- Travel time
- Frequency of departures
- Timing of departures
- Day of week
- Service delay

Figure 1 ARP demand-driven factors.

such as the levels of foreign trade, exchange rates and the whole economic situation of the endpoint regions are also taken into account (Lohmann and Vianna, 2016).

Airline service-related factors impacting the demand include the level of comfort of the aircraft, the fleet capacity and range, the presence of in-flight amenities, frequent flyer programs, the airlines' safety records and the passengers' perceptions of safety, and the price of airfares. There are also several other factors directly related to how passengers value their time, including the total travel time, the frequency and timing of departures, the days of the week when the service is available, as well as the level of service delays. Fig. 1 depicts these air route demand factors.

Supply-Driven Factors

While demand may be a necessary factor in the availability of air services, this may not be sufficient to make an air route feasible. Airlines pay close attention to a series of additional circumstances before reaching a final decision, as these may impose severe restrictions on operations. These can be divided into seven major groups (Fig. 2): political, socio-cultural, geographic, touristic, economic, market, and operational factors. The following discussion is based on the findings of Valente and Lohmann (2005), and Lohmann and Vianna (2016):

1. Political factors—relating to the broader geopolitical negotiations between two or more countries, including the social instability of the destination—such as the existence of wars, the threat of terrorism or internal or religious conflicts. In addition, air transport

Air Route Supply**Touristic factors**

regulatory frameworks fostering air traffic rights can be included here. For example, multi/bilateral air service agreements, open skies and/or liberalization of the air transportation market.

2. Socio-cultural factors—encompassing travelers' profiles (such as age or income) and behaviors (e.g., preference for certain type of aircraft); the airline's relationship with further stakeholders in the region.
3. Geographic factors—comprehending the route distance in terms of the locations of the destinations, the topographies (accessibility and ease of mobility) and geomorphologies (urban environments, islands and archipelagos, mountainous or rural areas), and climate, influencing not only aircraft operations but also peoples' desire for travel.
4. Tourism-related aspects—consisting of the type of tourism segment offered, including the competitiveness of the destination (e.g., the quality of lodging, catering, recreation and leisure facilities), expected length of stay, seasonality, directionality of passenger traffic between the two ends of the route, appeal and awareness of the destination, the current stage of the destination's life cycle (emerging vs. mature); and the existence of the appropriate tourism infrastructure and features which are attractive to visitors and influence their length of stay.
5. Economic factors—associated with the economic situation of the endpoint cities of the routes, the economic forecasts, the existence of airport financial incentives, the overall level of taxation, the expected traffic density on the route, as well as possible ranges in price of airfares to be charged, aircraft load factors, estimated costs of operating the route, and the potential for cargo freight.
6. Market characteristics—comprising competition from other airlines or other modes of transportation, the reputation and image of the airline (which can be affected by the failure of a route development endeavor), advertisement costs and potential spillover gains in publicity for the company.
7. Operational factors—comprehending the appropriateness of available aircraft capacity/limitations to operate the route, the current schedules of aircraft and staff, the costs/benefits of using new technology, airport infrastructure and constraints, including the length of the runway, slot/gate availability, existence of curfews and levels of congestion, location of the airport and the presence of competing airports in the same city or in its surroundings, the network contribution of a new route and its potential for providing feeder traffic at an airline's hub (allowing cross-subsidization of routes), and, not least, the company's business strategy.

Air Route Development (ARD)

Turning our attention to the ARD process, particular emphasis on the role air transportation stakeholders play is fundamental. Traditionally an initiative led by airlines, this process has undergone some significant changes over the years, as other stakeholders have become more and more involved, in particular in the early stage of demand exploration. Especially since the 1990s, airports have become progressively more commercially oriented. This has followed a series of global privatization efforts, seeing airports take a central role in the responsibility for and interest in promoting new routes, improving airlines' choice of aircraft, and increasing the frequency of services.

However, it is important to note that the ARD process may yet assume a range of broader objectives than the ones cited—ultimately depending on the nature of the airport operator and its relationship with the other parties involved. These may include improving air access, the capacity and the economic development of a community or region, or even retaining air services on current routes that may be at risk of suspension. While ARD is undoubtedly a growing commercial activity across the globe, individual countries like Singapore and the UAE have been particularly successful, notably in terms of cooperation and collaboration amongst various key stakeholders (Lohmann et al., 2009, Spasojevic and Lohmann, 2019).

Stakeholders' Engagement

Evidence from the literature has suggested that ARD initiatives are associated with the successful financial performance of airports, in recent times becoming increasingly more important for their profitability (Halpern and Graham, 2016). ARD may have a prominent role on the significant increase of non-aviation revenues from the increase number of passengers' consumption at airports, as well as additional revenues derived from airport charges. Moreover, these benefits may not be confined only to the airport, as spillover effects such as employment, tourism, trade and business opportunities may manifest throughout their surrounding regions, making airports key influential players in regional development.

In light of this, the growing involvement and influence of additional stakeholders in ARD can be easily understood. Furthermore, it is apparent that this change in paradigm has been well received by airlines, with evidence from recent studies indicating that the most important factor for an airline in operating a given route (after its profitability) is a good relationship with the relevant stakeholders (Stephenson et al., 2018).

Although airports are recognized as the leading stakeholders in ARD, the literature has suggested that tourism organizations are their most reliable partners (Stephenson et al., 2018). This is to be expected, as both airports and destination management organizations (DMOs) present similar objectives, rendering the whole partnership mutually beneficial. Nevertheless, other secondary stakeholders can also be mentioned which although not essential to the process, can impact the level of success and the efficiency of the desired outcome. These secondary stakeholders include local authorities, chambers of commerce, regional development organizations, other airports, and the various organizations comprising the tourism production chain (e.g., travel agencies, tourism

operators, hotels, event organizers, tourist transport providers, among others). All these stakeholders, primary and secondary, are presented in [Fig. 3](#).

So far, this chapter has predominantly focused on how airlines engage with ARP. We now focus more specifically on the unique roles that DMOs and airports play in ARD.

Destination Management Organizations (DMOs)

Destination management organizations (DMOs) are specific bodies responsible for the development of tourism in a particular destination or area, and they are commonly established by local, regional, state, or national governments.

Given these characteristics, DMOs are provided with considerable political power, which they deploy by leading and coordinating the promotion of destinations along with airlines (employing marketing strategies, for example). Besides, DMOs may also be in a position to engage local businesses to influence the demand of a region, reducing the uncertainties associated with the operation of routes to or from it. In some cases, an airline may go as far as to seek collaboration when a route is not performing well, but they still may want to invest in it. In this way, these stakeholders also have a role in avoiding route suspensions ([Lohmann and Vianna, 2016](#)).

We note that such DMO initiatives will have their greatest impacts in the cases of smaller airports, where the chance of success is expected to be lower, given that these airports have limited budgets along with smaller markets and potential demands, making the additional engagement of stakeholders crucial. However, convincing airlines to establish new routes to regional destinations has its challenges and risks, with airlines favoring the main capital cities and metropolises.

Airports

Of all stakeholders, airports provide the strongest link to airlines, as symbiotic relations between them commonly emerge, reflected through several types of agreements which have come into being in the industry over the years. These include an airport having a signatory airline; the airline having ownership or control over airport facilities or signing a contract for long-term use; employment of airport revenue bonds to airlines; as well as revenue sharing between these two actors.

Airport managers' in-depth knowledge of the local infrastructure and the travel habits of their catchment area population confers a central role upon them, enabling them to engage a wide range of stakeholders and facilitate the creation, promotion, and amplification of ARD strategies to attract airline services.

[Halpern and Graham \(2015\)](#) indicate that the vast majority of airports are actively involved in route development initiatives, with the level of involvement being higher for larger airports, predominantly those located in the United States and Europe. Moreover, concerning ownership, results indicate that about 47% of publicly funded airports retain a route development team, with this proportion increasing to about 86% in airports operated by the private sector.

As airports compete for more and more limited airline capacity, they may resort to the use of incentives to attract or retain airlines, such as offering discounted charges for the use of their infrastructure. Notably, this appears to be widespread in Europe and the United States and at airports of all sizes, no matter whether publicly or privately owned, as indicated by research in this field.

Two main objectives commonly underlie the use of incentives for ARD: (1) route growth initiatives, associated with the addition of new destinations, and (2) volume growth initiatives, related to the development of passenger throughput, higher flight frequencies and/or greater aircraft capacities. Furthermore, the types of incentives that can be offered are broadly classified into financial and non-financial. Financial incentives can include direct payments made on a flight or passenger basis, direct payments made through a marketing budget where joint advertising and promotional campaigns for a new air service may be offered, discounts on airport charges, property rental and/or taxation, and risk sharing arrangements such as revenue guarantees, travel banks, and/or joint ventures. Non-financial incentives may involve regulatory and/or market information, the provision of contacts to feeder airlines, service providers, agents, tourism organizations, DMOs and the media, and aiding other stakeholders

in better serving these airlines. Additionally, airports may still offer support through lobbying activities, particularly concerning traffic rights and capacity obstacles.

Incentives can be a particularly relevant measure for attracting low-cost airlines, as charges may account for approximately 10% of their total operating costs. To reduce an airline's financial risks, in this way, the presence of incentives can be crucial for the economic viability of some routes, at least during their start-up phases. In addition, these incentives may even be justified, provided that carriers continue their air services after the incentives expire, as airlines may make considerable investments in a particular airport.

The Steps of the ARP and ARD Processes and Their Integration

After describing the significant factors considered by airlines in their planning of an air route and the primary stakeholders involved in the ARD process, as well as their roles and objectives, this section considers the steps taken through both processes. The discussion is based on Valente and Lohmann (2005), Halpern and Graham (2016), Stephenson et al. (2018), and an ASM Global Route Development (n.d.) White Paper devoted to the ARD process. While not particularly emphasized in this section, it is worth considering that the ways in which stakeholders will engage depends on the importance of the airport/city in terms of attracting new routes, the regulatory framework in place and the governance and leadership style of the organizations involved. Spasojevic et al. (2019) provide a thorough analysis of the leadership and governance attributes influencing ARD across several regions throughout the world.

From the airline's perspective, ARP can be seen as an on-going process, manifested through the addition and/or removal of routes or changes in the frequency of services, ultimately creating the 'structure' of the airline's network. This whole process is depicted in the middle column of Fig. 4. It begins with a route solicitation for the airline's route planning department, which may

Figure 4 The steps of the ARP and ARD processes.

be internal (usually advanced by the airline's marketing and sales department) or external (promoted by air transportation stakeholders). After that, as described in Section Air Route Planning, the relevant supply factors to be considered are selected and carefully analyzed. In the case of an opportunity being verified, the planning department will then conduct preliminary surveys about the feasibility of operating the market. Having technical and operational responsibilities, it will provide analyses of the best fleet to be used, how the route fits into the airline's network, the costs to be incurred, expected yield, number of staff required, and the necessity (or possibility) of intermediate stops. The planning department (or, depending on the airline, its board of directors), may decide for the operation of the route or against it, possibly being persuaded by stakeholders who are regularly involved in the whole process. Regardless of the decision to start or not a route, airlines will be in possession of critical intelligence data, eventually only waiting for the right moment for developing a particular route. Having decided on its operation, the process is advanced to the phase of operational planning, consisting of activities related to network planning, fleet assignment, aircraft routing and crew rostering.

New routes are implemented after being thoroughly planned, and they become part of the set of markets operated by the airline, contributing to the achievement of the network's development. However, the control and feedback stage of the company's performance is still crucial. If the targeted market share and profit do not match expected values, the company may need to revisit its strategy. Moreover, the company's performance may influence a set of the air route supply factors, more importantly, operational and/or economic factors which are necessary for the operation of the new route and even of the other routes in its network. Likewise, supply factors may also influence a company's performance, with the market, political, and social factors being particularly impactful.

Turning our attention to the ARD process, this also constitutes a constant process from the perspective of the various stakeholders, and it occurs in parallel with the ARP process. It is depicted in [Figure 4](#), in the right column. This process begins with the identification of the objectives of the route development, be it by the achievement of connectivity or traffic targets and many more of the broader objectives related to regional impacts, as listed in Section Air Route Development.

Having identified the objectives, a route development team will take matters of the process. This team will be responsible for three critical tasks—that of market research and forecast; negotiation and relationship management (i.e., the attraction of new airlines); and marketing (the creation of awareness and building of passenger numbers). The route development team will begin by undertaking a primary assessment of the size of the region's catchment area and hence quantify the potential demand for air travel. The necessary information will include the population size, residents' characteristics, their propensity for travel (or in other words, the factors influencing outbound traffic) and the region's tourism and business appeal (the factors affecting inbound traffic). Similar to the route planning department of an airline, the same set of factors will be selected and analyzed, and the resulting information will be compared with current operations to identify unserved or underserved routes and the potential market share to be achieved. At this stage, it is crucial to be realistic about the whole process, as overambitious ARD on ultimately unsustainable routes can have appalling effects on traffic development at an airport in the long run. It is important to remember the existence of a path-dependency in the development of air services, as preceding route development actions may limit the capacity of change of subsequent ones. In other words, there may be multiple optimal actions at any given time, but not all of those will lead to an optimal solution in the long-run—implying the possibility of increased levels of service by the appropriate selection of routes to be developed at each period ([Kita et al., 2005](#)). As a follow-up, an analysis of the competition will be conducted. An understanding of other airports in the analyzed catchment area (e.g., their market segments, relative performances or relative airfares) will be essential. Additionally, an assessment of other transport options; competing stakeholders; and even of communications technology possibilities (e.g., video chat and voice call applications) can be implemented, in order to better quantify the market potential (accounting for all possible factors which may reduce it). Finally, the team will analyze which airlines may be suitable to operate the new route and will produce a financial viability assessment, taking their business models into consideration.

With all this information in place, the route development team will communicate it to the target airlines, making service solicitations (in the case of a new market to be operated by that carrier) or a solicitation for change in existing services. At this stage, ARD opportunities will be marketed, usually through the presentation of a business case at the airline's offices. As previously mentioned, this can be interpreted as an external route solicitation. Price incentives and marketing support may also be established at this stage. A good relation with DMOs pays off at this stage, as the promotion of the destination (as opposed to the airport infrastructure) will be key for a favorable outcome of the negotiation.

Having presented the opportunities, stakeholders will stay engaged in the process, trying to influence airlines to begin or retain operations on a given route. To get the most out of this stage, it is essential for stakeholders to determine processes and procedures for dealing with airlines at all stages of ARD from their first contact, from the launch of a new or a changed route, to on-going care necessary to ensure that route opportunities are maximized and a long-term relationship is established and maintained. At this stage, stakeholders may also be involved in actions focused on avoiding route suspensions, through their influence over many of the supply factors presented in Section Air Route Planning (the touristic, political, and social factors being the most obvious ones). Particularly in the case of an airport, the offer of additional financial and/or non-financial incentives may also take place at this stage.

Lastly, it is vital that stakeholders be aware of how well airlines are performing within the entire portfolio of the markets in which they operate—and especially in those influenced by their initiatives. The establishment, maintenance, and growth of new services all require ongoing evaluations. Although airports may assume a leading role at this stage, the fact is that stakeholders must control and evaluate their ARD efforts, while also assessing the performance of individual routes on a regular basis to understand whether there is

indeed progress, identifying issues or problems and addressing them before they become worse. For continued success, ongoing route-performance analysis is crucial, as is a long-term relationship with the airlines. The results provided by this control and evaluation stage will then be fed into the setting of new or revised objectives, the first stage of the stakeholders' ARD process, thus closing the cycle. Likewise, such results will also offer relevant information about the possible avoidance of route suspensions (also associated with the stakeholder engagement stage).

Summary and Conclusions

The establishment of new routes, particularly on previously unexplored markets, offers some important challenges for airlines. This requires thorough planning with a careful estimation of the potential demand as well as a precise understanding of the conditions which must be met to provide a sustained market development. To the same extent, it also requires a critical analysis of the factors, from both the demand and supply sides, that influence market growth and are beyond the control of the airline. Such collection of intelligence data is an important step in the airline internal process of ARP. However, external stakeholders have been playing an increasingly important role in such endeavors on what has been called the ARD process. Airports, progressively more commercially-oriented, especially after a worldwide privatization trend around the world, have had a central role in such activities, as these have acquired a greater role in the profitability of their operations. In partnership with DMOs, airports have enabled the reduction of financial risks for many airlines, providing many spillover effects for regional development. ARP and ARD, nevertheless, do not function in isolation or are finished after the initiation of a target route. On the contrary, these are ongoing, cyclic and parallel processes. For continued success, ongoing route-performance analysis is crucial, irrespective of the process being carried out internally or externally to the airline, as is a long-term relationship between the airlines and the stakeholders.

Introduction

Airline management is the organization and coordination of all airline activities to achieve some defined objectives and goals. Strategies are employed by managers to help the airline to get to the objective within the timeframe and resources allocated. The management of airlines involves the integration of many functions through policy, organizing, planning, controlling, and directing of resources toward an objective. Thus, airline managers deal with both internal and external variables, some of which can be manipulated, but in other cases the managers can only anticipate changes and react. This paper is divided into two parts the *internal environment* and the *external environment*. Part 1, internal environment, contains the following: strategy, product, distribution and promotion, operations and network, pricing and markets, and organization and human resources. Part 2, external environment, contains the following: regulation, the economy, political climate, taxation, and societal changes.

Internal Environment

The key internal variables for airline management are strategy, product, distribution and promotion, operations and network, pricing and markets, as well as organization and human resources.

Strategy

The world's air transport liberalization trend started with the advent of the Airline Deregulation Act of 1978 in the United States. Not only was this the start of a worldwide regulatory reformation in air transport but also a new era of segmented business models. Before deregulation airlines were segmented into full-service carriers, regional carriers, cargo carriers and charters. However, after deregulation the low-cost business model took off, usually cloned on Southwest Airlines, a carrier that had thrived in the liberalized Texas intrastate market before deregulation took place. A large part of air transport growth and new services in deregulated domestic markets can be traced to these carriers.

There are two generic strategies that polarize the airlines and their business models today, namely cost leadership and differentiation (Porter, 1980). The former strategy tries to achieve the lowest possible costs in order to offer very low fares. What defined this strategy for the airlines was the attempt by Southwest Airlines to compete with cars and buses on short-haul secondary markets in the Texas intrastate market. In order to generate such new demand costs had to be very low to offer low enough fares to pull people out of their cars (Gudmundsson, 1998). This has been termed as the *Southwest Effect* (Bennett and Craun, 1993) and denotes the price level where a rapid increase occurs in demand on a particular route. The Southwest Effect also explains why most low-cost airlines do not charge monopoly prices on monopoly routes, unlike the full service carriers.

To achieve very low-cost in comparison with the differentiators, low-cost airlines offer fewer service features than the full service airlines, and operate predominantly point-to-point services to secondary cities. Simplification of operations keeps costs down by avoiding both the direct and indirect costs of performing "unnecessary" activities. In this way a low-cost airline only offers services that matter the most to the customer, a seat between A and B, that parts on time. However, over time both low-cost and full service airlines have focused on increasing revenues through unbundling of services. For example, by charging fees for: priority boarding, emergency exits seats with more legroom, food and beverages on board, and hold baggage. Low-cost airlines will normally offer extra services as well, so far as the associated activity does not cause complexity in operations incurring added direct and indirect costs. For example, most low-cost airlines will not offer connection services, or business class seats. In this way, unbundling causes convergence of low-cost and network carrier services in the mind of the customer. To come to the point, low-cost airlines will strive to maintain high fit between all activities performed to keep the cost structure low.

Full service carriers differ by offering a wider range of service features and more extensive customer care. What is more, such carriers usually operate long-haul routes and hub and spoke networks to generate economies of scope and density that boost aircraft load factors. Hub and spoke means hauling passengers and cargo from many points of origin to many destinations through a single centre, the hub airport (Oum and Tretheway, 1990). Thus, full service carriers use differentiation strategy based on the assumption that customers are willing to pay a premium price for more service features and high connectivity. This is especially true for business travelers that fly on behalf of their companies. Today's full service carriers offer an extensive global network through branded alliances, such as skyteam, oneworld, and Star, to help meet the total travel needs of the customers and assure seamless connections between the alliance partners.

The low-cost business model was an important innovation enabling new carriers to enter liberalized air transport markets and mount effective competition with the full service carriers in domestic markets. However, the low-cost model works well on point to point short haul routes, but has not enjoyed the same success on long-haul routes, a market that still remains the key competitive advantage of the full service carriers. In other words, there appears to be a mobility barrier traversing from a low-cost to a full service network carrier. A mobility barrier (Mascarenhas and Aaker, 1989) refers to obstacles in moving from one strategic group of firms (low-cost carriers) within an industry to another group (network carriers) and may include barriers to entry, barriers to exit, barriers to changes in market position, and barriers embedded in cohesive business models.

Product

Whereas, a low-cost airline may offer only the most important product features sought by the customer, a full service carrier will offer a wide range of features fitting a more expansive network of both short-haul and long-haul flights, such as food on board, airport lounges, frequent flyer programs, network connectivity, and ticket flexibility. Thus, the product is strongly influenced by the generic strategy of the airline.

The elemental product attributes of a low-cost airline are safety, reliability, punctuality point-to-point service, low fare, flexible baggage allowance, hold bag fee, one-way fares, a variety of food and beverages for sale, priority boarding for a fee, and selling insurance to reduce customer's perceived risk if flights are late or cancelled. For full service network carriers we can add some important service differences such as a global network through alliances, seamless connections throughout the world, frequent flyer programs that reward the most valuable customers with personal benefits such as free flights, assistance and rerouting in case of missed flights, and so forth. Defining all the different product features of airlines to place them in either the low-cost or the full service categories is becoming somewhat blurred as low-cost and full service airlines have unbundled the product and new business models have emerged that can be considered hybrid (Mason and Morrison, 2008). In other words, airline business models are now more blurred, but the key difference between airlines of different origins, low-cost or full service, remains the hub-and-spoke versus point-to-point and long-haul versus short-haul.

Distribution and Promotion

The largest global distribution systems (GDS) are Amadeus, Sabre and Travelport (Galileo, Worldspan and Apollo), but there are also a regional GDSs like Travelsky in China, and KIU System in Latin America (Williams and Rhoades, 2017). In the past airlines

extended their own internal computer reservations systems (CRS) to travel agencies, but with time these became independent businesses that access the internal seat inventories of practically all airlines. Although airlines are increasingly emphasizing booking through their own websites, the GDS still plays a role as a “one-stop-shop” for complex travel needs, such as multiple-itineraries involving airline interlining as well as hotels and other travel services, and for travel agencies specializing in corporate travel management. Today’s GDS systems are designed to interoperate with all major airline systems, and provide total IT system solutions to the airlines. Thus, GDS will exist in one form or another but the airline distribution industry has become much more segmented than in the past when the GDSs operated in an oligopolistic market.

Today, a larger and larger proportion of flights is booked by customers themselves through internet booking sites either the website of the airline itself or non-GDS virtual booking sites. Disintermediation takes place when airlines try to circumvent intermediaries like travel agencies and GDS. However, despite disintermediation in terms of GDS sales and travel agents, another type of intermediation appeared in the form of websites that indexed airline offers through the search engines (Kracht and Wang, 2010). Such virtual intermediaries provide customers with a comparison of a broad selection of flights and fares that is otherwise only available to travel agents using the GDS systems. Thus, virtual intermediaries provide information transparency about fares and services that would otherwise be tedious to unravel for customers using the internet for flight bookings.

Operations and Network

Operations

Maximizing operating profits through optimum use of resources is the global objective of airline operations management. Thus, airline operations strive to match aircraft capacity to demand, and maximize productivity of the resources used, especially the aircraft and the employees. US FAA regulation Part 135 specifies maximum pilot duty period as 1200 flight hours in any calendar year, 120 flight hours in any calendar month, and 34 flight hours in any 7 consecutive days, putting major constraints on how pilots are allocated, in addition to aircraft type ratings they possess. Thus, airline operations are occupied with employing the right aircrafts, scheduling to maximize daily utilization, fulfill maintenance requirements and mandatory checks, assign the right crew (duty times and qualifications), and to assure smooth turnarounds at airports (ground handling). Airline operations managers strive to optimize schedules so that slack (aircraft on the ground) is minimized. However, the lower the slack in the schedule the greater the effect of delays (weather delays, aircraft breakdowns, etc.) in the network, affecting aircraft availability, crews pairing (duty times and pilot qualifications) and passengers (missed connecting flights, etc.). A major disruption of airline schedules can take days to correct due to domino effects (Kohl et al., 2007).

Aircraft have four levels of mandatory inspections (A, B, C, D) that are accounted for in the annual scheduling of aircraft (Lee et al., 2008). The A Check is roughly once a week or approximately every 60 flight hours; the B Check is once a month or every 300–500 flight hours; the C Check is performed after approximately 1800 flight hours or 2000 cycles and takes between 3 and 5 weeks; and the D Check is a major check that involves dismantling parts of the aircraft for detail inspection of its metal skin, structure and systems. The D Check can involve up to 50 thousand man-hours over 8–12 weeks and is performed every 6–12 years depending on aircraft type and age.

Network

Airline networks are at three levels: airline route networks, alliance route networks, and global route networks (Hsu and Shih, 2008). Airline route networks are shaped by airline strategy, demand, available fleet, marketing and sales. Whereas low-cost airlines tend to operate only point-to-point networks with limited if any network extension through alliances, the network carriers usually have extensive alliance relations and intercontinental long-haul routes. When designing alliance route networks much emphasis is on global network coverage and seamless connections in major airports. This is one key difference between low-cost and network airlines that remains difficult for low-cost airline to duplicate, for two principal reasons: First, low-cost airlines rarely operate hub and spoke networks as these can affect negatively on aircraft utilization. As the arriving and departing banks of aircraft become larger in hub and spoke airports, the ground time of aircraft tends to increase, increasing operating costs because of lower aircraft utilization. Second, low-cost airlines tend to keep costs down by operating a single type of aircraft aimed at short to medium haul routes and quick turnarounds, avoiding long-haul aircraft that are more costly to operate. In other words, network carriers seek economies of density and scope through hubs, while low-cost airlines seek *Southwest Effect* through very low fares in secondary point-to-point markets.

Over time the global airline route network has become dense with more and more communities being served, mostly by low-cost and regional airlines operating into secondary airports. What is more, with increased congestion in major airports, frequencies and new services have spilled over to other less congested major airports and secondary airports (Gudmundsson et al., 2014; Redondi and Gudmundsson, 2016). Thus, air transport services are more accessible for larger and larger part of the global population, but increased network density means also that more and more communities resist airport infrastructure expansion due to environmental and health concerns.

Pricing and Markets

Elasticity of Demand

Price elasticity of demand for air transport differs because passengers fly for different reasons and have different income levels and are often flying on behalf of employers rather than for own funds. Thus, we broadly distinguish between business and leisure travelers.

Whereas, leisure travelers strive to maximize income constrained utility and holiday experiences, business travel is an input in the firm's operations, and time and service levels usually play a greater role than price. Thus, the marginal utility of air travel differs between the two segments causing different demand sensitivities to two relationships, namely time over price and price over time. Thus, business travel, on average, tends to be less price elastic than demand for leisure travel (Castelli et al., 2003). For these reasons, understanding the price elasticity of demand for different markets is essential for pricing and supply decisions in the airlines.

Market Selection

Market selection, the destinations the airline serves, is one of the key decision variables in airline management. No market is the same in how it reacts to airline offerings and prices. For this reason, airlines analyse markets carefully by assessing demographic information such as income levels (see Calzada and Fageda, 2019), type of businesses operating in the area, population size and growth, political composition of the population, minorities and proportion of foreign origin residents, average and disposable income by customer segments, regional economic growth, and so forth. With this information combined with historical data the airline can predict market reaction to different fare classes, such as leisure, visiting friends and relatives, and business travel. For a low-cost airline, the most important aspect of analyzing markets is to determine at what price the *Southwest Effect* kicks in, namely a kink in the demand curve that represents price-market stimulation.

Revenue Management

Airlines have since the 1980s utilized sophisticated information systems to determine fare offerings, the so-called yield management system that sits on top of the internal computer reservation system (see Smith et al., 1992). Such systems allow the airline to maximize average revenue per flight by varying fares based on seat demand and the propensity to pay by different customer segments. Some segments are time sensitive while other segments are price sensitive. Based on this information the yield management system attempts to separate the segments as much as possible to prevent sales cannibalization between the various customer segments. For these reasons, most network carriers will retain as many high fare seats as possible close to departure, as business passengers are most likely to book flights late and are not as price sensitive. However, if too many high fare seats are blocked and demand does not materialize, airlines use overbookings to avoid spill (fly empty seats) (see Swan, 2002). When overbooking the airlines seek to maintain a balance where the gains from overbookings are larger than the costs and penalties incurred due to passenger rights regulation existing in some countries.

Just like full service carriers, low-cost carriers also operate yield management systems, but these tend to be simpler and with some notable strategic differences (see Dunleavy and Westermann, 2005). For example, low-cost carriers may try to capture last minute price sensitive customers from the full service carriers by offering much lower last minute fares. Such carriers also offer one-way fares that are not much different from the round trip fares, that is, the roundtrip fare is simply a combination of two one-way fares. Whereas full service carriers, tend to charge much higher one-way fares as proportion of the round trip fare. On the other hand, low-cost carriers do not offer multi-segment fares, whereas full service carriers frequently offer attractive multi-segment fares.

Organization and Human Resources

Human Resources

Airlines are labor intensive and there is a strong linear relationship between the number of aircraft operated and the number of employees. Despite this, average salaries per employee can vary greatly between airlines, even in the same country. What is more, productivity per employee can also vary substantially, explaining dramatic differences between airline cost structures and performance. Some low-cost airlines may have similar average salaries, but large differences in productivity, thus remaining low-cost by making much better use of human resources, despite higher salaries. One element that contributes to such a difference is simplicity of operations, by only performing activities that are necessary to offer the service features the passenger values the most. It is for this reason that low-cost airlines avoid offering business class seats, connecting flights, long-haul flights, and to operate multitype aircraft fleets.

Organization

Full service airlines are organized and structured to offer a full line of services and to innovate to enhance customer value at a price premium. The low-cost airlines, however, organize to keep costs in check and innovate to reduce costs, yet they strive to command high price-value perception on the service features offered. Despite low-cost airlines focusing so much on costs, they increasingly innovate to generate ancillary revenues, through unbundling of the product and acting as intermediaries for associated services such as insurance, car rentals, hotels and even train or bus tickets to and from airports.

External Environment

The key external variables influencing airline management are regulation, the economy, political climate, taxation, and societal changes. Airlines also face extraordinary events that are difficult to foresee in terms of timing and impact. Examples of such global impact events are terrorism such as 9/11 and the 2008 Credit Crises. There are also external events that are specific to the airline

industry such as long delivery delays of new aircraft (e.g., A380 and B787) as well as grounding of an entire fleet of aircraft types for safety reasons (e.g., DC10 and B737max) that can cause major financial hardship for the airlines and customer relations issues due to schedule disruptions.

Regulation

The State of California, as early as 1946 promoted the liberalization of its air transport intrastate market by allowing free entry and price competition, leading to the entry of 18 airlines in the period between 1946 and 1965 (Entry was free until the Cal. Stat. Act of June 17, 1965, ch. 736, 1965), many with different business models. The State of Texas followed by allowing price competition in its intrastate market. Several efficient airlines emerged from the pre-deregulation period such as PSA (1949–88), Air California (founded 1967–87, merged with American Airlines) and Southwest Airlines (founded 1967). The two States, California and Texas, therefore became the showcase for the impact of liberalized air transport on fares and used as examples by the proponents of full deregulation (Levine, 1965; Jordan, 1970). There is no doubt that liberalization in these two states provided consumers with the lowest airfares in the world, stimulating a major increase in passenger volumes. Liberalization, according to the proponents, increased consumer welfare, increased airline efficiency, and was in the public interest.

The 1978 Deregulation Act in the US domestic market spearheaded the liberalization trend in air transport. However, over the several decades since, other regulatory reforms in air transport have taken place: liberalized air services agreements in associated services such as ground handling, and regional liberalization spanning two or more countries, the so-called *open aviation areas*. Observing air transport deregulation in the United States, the EU followed suit through three packages of liberalization, implemented between 1987 and 1997 (Gudmundsson, 2011, 2019).

The best examples of liberalization in international air transport are the *Open Skies* air services agreements between the EU countries and the United States, the ground-handling liberalization in the EU is an example of liberalization of associated services, while the European Common Aviation Area (ECAA) and the Open Aviation Area (OAA) are examples of regional liberalization.

The Economy

Airline managers take into account potential fluctuations in the economy in order to manage the negative influence on the airline's profitability. There are two major influencing factors, oil prices and economic downturns. Although these two correlate, changes in fuel prices tend to have an immediate effect on the airlines finances, whereas downturns, causing reduction in demand, may involve some lag. The influence of the economic factors tends to differ on the two main strategic groups. In some cases, the low-cost airlines may benefit from economic downturns, as individuals and firms reduce costs by shifting to low fare airlines. At the same time, the leading low-cost airlines enjoy higher average margins, creating a buffer against cost increases and demand shifts. Full service carriers, as a strategic group, are more likely to experience losses during economic recessions because of thinner margins. Among these, full service carriers that are most resilient against economic shifts tend to be the most productive in terms of low input costs and high revenues per output unit or employee.

Political Climate

In the early 1970s the world economy was hit by a hike in oil prices and decline in consumer confidence. These events helped shift politics to consumer advocacy and away from the protectionist climate that had ruled many industries, including the airlines. It was in this backdrop that deregulation gained momentum in the US. Advocates of deregulation pointed out that the airlines had never been profitable (PBS, 2008) because regulation prevented price competition causing the airlines to fly half-empty planes in price sensitive markets. Even though the airlines were generally not keen on deregulation they suffered from overcapacity in the early 1970s that could be alleviated by stimulating extra demand through attractive discount fares. However, the CAB had stood in the way of such moves by the airlines. One of the key proponents of deregulation Alfred Kahn, stated that the government had to get out of the way of the market forces. Politicians at the time saw such change as a way to counter rising inflation by increasing fare competition. In other, words deregulating the airlines were seen as counter-inflationary as the US economy battled with the inflationary effects of the oil crisis (Gudmundsson, 2011).

The political event that rolled the ball in this direction was The Kennedy Hearings in 1975. The Civil Aeronautics Board (CAB) created the so called "route moratorium" by not granting any new routes since the late 1960s due to over capacity. Thus, within its mandate of maintaining industry stability, it did not grant new route rights unless public need was proven, rarely the case. The Kennedy Hearings, contrary to the CAB view, argued that the CAB's policies were preventing public access to affordable air fares. The view that emerged was that protectionism affected costs and prices because of lack of competition and innovation in the industry hindering its progression (Gudmundsson, 2011).

The CAB had stabilized the industry and market-shares of the major players, but it inhibited the ability of the airlines to benefit larger segments of the public through competitive prices. Society had changed and new expectations emerged that called for a more competitive industry. By deregulating pricing decisions, fares would approach the marginal costs at the same time that stronger incentives to improve resource utilization would push down costs. Thus, service, costs and price should be left to the market economy (Kahn, 1990). Although regulation was often seen as a cure to market failures (Levine, 1981) and instability (Keeler, 1984),

increasing evidence showed the opposite (Levine, 1965; Jordan, 1970). Thus, theories of deregulated markets were put to a test in a climate of political support and the airline industry was a high profile testbed for these ideas.

The EU followed suit, but much later and through a markedly different political process. The European Coal and Steel Community (est. 1951) was the first step in a long process to integrate Europe with the aim to stabilize the volatile political forces post WWII. The European Economic Community (EEC) was the second step, formally established through the Treaty of Rome in 1957 with the aim of dismantling the economic borders in Europe. The third step was to dismantle the political and social borders by establishing the European Union (EU) in 1993 through the Maastricht Treaty (sign. 1992).

Many European countries saw the model of big government and heavy control as ineffective in meeting changing public needs, especially when compared to Germany that was growing its industry at a faster phase than most other EU nations. In this climate the role of government was seen as hindering value creation in a more complex society where regulating pricing and supply of industries was questioned. Although the political climate and theories behind these changes went through reevaluation in the post-Thatcher-Reagan era, few argue for the comeback of economic reregulation of the air transport industry.

There are several important events that enabled air transport liberalization in the EU (Gudmundsson, 2011): (1) The *Nouvelles Frontières* case (Ministre Public v Asjes, Cases 209-13/84) that led to the 1985 decision of the European Court of Justice to rule that Article 81 was applicable, rendering approval of airfares by a Member State unlawful; (2) the 1985 Schengen Agreement (implemented in 1995); (3) the Commission's first White Paper on future development of common transport policy; (4) the Bosman ruling on free movement of people in 1995; and (5) the "open skies" judgments in 2002, stating that Member States cannot act in isolation when negotiating international air services agreements. All of these events, especially the *Nouvelles Frontières* ruling, facilitated liberalization and growth of air transport in the EU by opening up markets, enable new entry low-cost airlines, and enable free flow of people between the member states.

The European Union is the amalgamation of very different countries with different legal systems and law, making integration through economic deregulation the most attractive approach to unification. Although air transport was exempt from Article 81 of the Treaty, it entered the jurisdiction of the European Commission in the 1980s, after the ruling in the *Nouvelle Frontières* case. The ruling of the European Court of Justice enabled the Commission to attack price fixing in air transport, to uphold the principle of free movement of people, and apply the anti-trust law to the industry. Consequently the governmental approval of IATA tariffs became anticompetitive and in conflict with both Articles 10 and 81 of the Treaty (Gudmundsson, 2011). These developments forced, the Member States to embark on gradual liberalization of air transport between 1987 and 1997, in three steps.

Taxation

Article 15 of the Chicago Convention states that no fees, dues or other charges shall be imposed by any contracting State in respect solely of the right of transit over or entry into or exit from its territory of any aircraft of a contracting State or persons or property thereon (Abeyratne, 1993).

There are two aspects to taxes in air transport, state taxes levied by the authorities on airlines, and taxes that the airlines add directly to fares. Airlines in some cases advertised fares that excluded taxes and fees levied on top of the basic fare. To address this issue the US DoT regulated airline advertising so that taxes listed separately are included in the advertisement on fares.

The tax situation on domestic flights is relatively straightforward. In the US an "excise" tax of 7.5% is levied on all domestic tickets and this tax must be included in advertised fares. However, in the US airlines exclude other government charges from published fares. On top of this airports can impose passenger facility charges (PFCs) up to a maximum of four different fees on a round-trip ticket.

On international tickets the US government levies a departure fee, an arrival fee on international tickets, an immigration and customs fee, as well as an animal and plant inspections fee. All of these fees are collected when tickets are sold.

In Europe a regulation was issued in 2008 laying down rules to improve transparency about taxes and charges disclosed in published ticket prices. Consequently, airlines are obliged to disclose final prices in advertising and in the reservations process.

State-aid is defined according to article 87 of the Treaty, as state grants, interest relief, tax relief (or relief of airport charges), state guarantee or holding, and provision by the state of goods and services on preferential terms. It was in the background of this article, that the European Commission, in 2004, decided that Ryanair had received concessions on airport taxes and fees, over fifteen years, in return for a certain throughput of passengers at Charleroi (Gröteke and Kerber, 2004). The arrangement was new in the sense that a low-cost airline and a regional airport worked together to mount effective competition with larger airports and airlines. In other words, the collaboration provided public benefit by offering competing services in an airport that was less convenient than the main airport. The case went in favour of Ryanair, although the European Court of Justice ruled that such offers had to be available to all airlines that served the airport.

Value Added Tax (VAT)

Airline tickets are generally exempt from VAT with the exception of domestic aviation in some countries (Keen and Strand, 2007). Aircraft are also VAT exempt in Europe if used by airlines on international routes. There is increasing pressure that air transport should incorporate negative externalities by eliminating the VAT exemptions of the industry (Graham and Shaw, 2008).

Fuel Tax

Aviation is generally exempt from fuel taxes in bilateral air services agreements since the expanding post-WWII years. Although a common practice in the industry it is a nonbinding resolution of the ICAO to include fuel tax exemptions in air services agreements.

Under the 2003 Energy Taxation Directive most fuels and energy products in the EU are subject to tax. However, the Directive permits member states the discretion to exempt aviation fuel. Most EU member states do not tax aviation fuel with the exception of the Netherlands, Norway and Switzerland that tax domestic aviation fuel.

State or local taxes on aviation fuel in the United States go to airports and are subject to revenue-use requirements. These can be used for the operating costs of the airport, the local airport system, or any other local facilities owned or operated by the airport. In addition to this, state taxes on fuel may be used to support state aviation programs. However, state sales taxes are not collected on airline tickets.

Environmental Taxes

According to ICAO Assembly Resolution A39-3 an environmental global market based measure (MBM) is one measure to achieve carbon-neutral growth for aviation from 2020 onwards. A global MBM scheme, the so called Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA), will address CO₂ emissions from international civil aviation that exceeds the 2020 levels. The CO₂ emissions from international aviation between 2019 and 2020 constitute the baseline that emissions in future years will be compared against. If in any year from 2021 international aviation CO₂ emissions exceed the baseline the difference must be offset for that year. However, there are several implementation phases of CORSIA (see [Scheelhaase et al., 2018](#)), and the first phase is voluntary, and some states are exempted from offsetting requirements: (1) pilot phase (from 2021 to 2023); first phase (from 2024 to 2026), and second phase (from 2027 to 2035). The second phase applies to all states that have international aviation output above 0.5% of total revenue tone kilometers (RTK) in 2018. Exemptions are least developed countries (LDCs), small island developing states (SIDS) and landlocked developing countries (LLDCs). However, any country can volunteer to participate in this phase.

An international route covered by the scheme must involve participating nations, otherwise it is not covered. Once participation of states and routes covered by the CORSIA is defined in a given year, and offsetting requirements (i.e., increased emissions beyond the average baseline emissions of 2019 and 2020) are set, the requirements are distributed among aircraft operators participating, according to a formula in the ICAO Assembly Resolution.

Other national schemes worth mentioning are environmental taxes that have been introduced in Sweden and Germany that levy a flat fee on every ticket sold with an aim to reduce the impact of air travel on the climate. The assumptions behind such taxes is twofold: (1) to reduce air travel by making it more expensive, a controversial approach as it affects the lower income groups in society proportionally more than higher income groups ([Shaw and Thomas, 2006](#)); and (2) to generate revenues that are used in state projects or to make tax refunds to individuals or firms that reduce their environmental footprint (electric cars, housing isolation, solar heating, sustainable energy, etc.) (see [Krenek and Schratzenstaller, 2016](#)). In Germany the green tax is distance related so tickets of more than 6000 km incur an extra charge. France has followed suit and a green tax on all tickets for outbound flights will take effect in 2020, to fund environmentally friendly transportation.

Societal Changes

Economic Wellbeing

Countries such as India and China have the benefit of rapid air transport growth over a long period reflecting policy changes that increase competition and lower air fares in combination with strong economic growth ([Wang et al., 2018](#)). Economic growth and market liberalization has impact on air transport demand in two ways: (1) increase in disposable income; and (2) the reduction in average air fares, making air travel affordable for more people. In the early days of air travel it was a transport mode for the elites, but as more and more capacity was added through larger aircraft, the airlines reduced air fares to fill more seats. In liberalized air transport markets, especially the US, EU and India, low-cost airlines have had a major impact in making air travel more affordable.

Price Elasticity of Demand

One other possible use of price elasticities of demand is for policy makers to predict policy effectiveness when formulating tax and environmental policies concerning aviation. Whereas, in past decades stimulating demand through increased competition and lower fares was seen as increasing social welfare, recently, environmental concerns and congestion has raised the policy makers' interest in demand reducing measures. Understanding the price elasticity of demand helps authorities to assess if air transport environmental taxes will reduce demand or simply increase the state's revenue from the industry ([Brons et al., 2002](#)).

Leisure

With increased consumer disposable income and travel experience, leisure travel has changed over time. For example in Europe in the 1970s and 1980s, a large proportion of the leisure traffic was between Northern and Southern Europe, especially Spain, Italy and Greece. This market then matured and in the 1990s and 2000s many charter carriers serving this market either went out of business or reoriented to meet their customers' wants for long-haul services to more exotic locations. Leisure travelers also took advantage of more attractive fares on the scheduled carriers that offered attractive package deals on city breaks all over the world. In this way the leisure market has become more diverse as travelers have become more accustomed to different cultures and more affordable air fares, more variety in hotel offers and higher quality tourism services around the world.

Migration

Air transport plays an important role in emigration by moving countries closer in time enabling people to keep contact with their origin and enjoy the benefits of living and working in another country. The origins of emigration vary, ranging from economic, social, political and conflicts reasons. There is also increased flow of knowledge workers that seek work where their competences are most valuable, no matter where in the world. Emigration also stimulates trade between an adopted country and country of origin. In this way emigration and related trade have major impact on air transport. In Germany for instance there are 2.8 million people of Turkish origin (Destatis, 2018), this is reflected in the fact that Germany is the number one destination of Turkish Airlines (Statista, 2019). Similarly, over two million Indian migrants live in the United Arab Emirates, an estimated 27% of the UAE population. Emirates Airlines of Dubai, serves a total of 9 Indian destinations with 170 weekly flights. What is more, the Emirates Group employs almost 14 thousand Indian nationals mostly in high-skill jobs, counting for 21% of its total workforce around the world (Emirates, 2019).

Education

Education has become highly internationalized with rising proportion of students in many countries being educated at distant national and foreign universities. This segment travels within own country or to and from country of origin. Students with more disposable income travel not only for their studies but also for study breaks, and also attract VFR traffic, as friends and relatives visit in vacation periods and attend graduations. A proportion of these students emigrates to the destination country and join the labor force as high-skill knowledge workers and reinforce in that way the VFR connection with the country of origin. As many as 1.1 million international students attend colleges and universities in the United States, and 334 thousand US citizens study abroad (IIE, 2019). In this way, air transport plays a role in improving accessibility and attracting high-skill labor force from other regions and countries. Academic institutions and air transport accessibility, in combination, play a crucial role in maintaining the competitiveness of regions and cities (Varga, 2000). In fact, research has shown that the air transport network stimulates more university location alternatives for students over longer distances and boosts regional human capital (Cattaneo et al., 2015).

Conclusion

Airlines are probably the most difficult business to manage, demonstrated in its challenging financial performance in comparison with most other industries. Airline managers must deal with many constraints and understand the industry practices and strategies that do not transfer readily from conventional economic theory or other industries. Due to these constraints, the job of an airline manager is probably one of the most difficult jobs to master. Warren Buffet, the investor stated once that despite all the investment in the airline industry the return in the long term is less than zero, thus, it is the most difficult industry to be in. Airline managers cannot rely on prescriptive rules of thumb on how to run their business but must adopt a dynamic and most importantly a deep understanding of the principles that guide effective strategic decisions in the airlines.

Airline managers must keep costs in check, no matter what the generic strategy of the airline, by assuring good fit among activities performed within the existing business model. In other words, an airline can undertake any activity or service feature so far as it does not cause major deterioration in fit. For example, fast turnaround of aircraft in airports helps increase aircraft utilization that in turn means fewer aircraft to serve the network, fewer pilots and therefore lower financing and crew costs. Thus, to maintain high fit among activities is the key to lowering costs and increasing productivity of the resources employed in an airline.

This being said the airline industry is one of the most exciting industries to work in and popular among young people looking for high profile entry level jobs with excellent career development opportunities.

Introduction

Delivering mail has historically been one of the first uses of aviation. Air cargo business has developed in parallel to the commercial passenger aviation, and currently represents a crucial part of some global value chains. Air cargo is also an important part of international trade. The share of internationally traded goods traveling by air is estimated at about 35% by value. Furthermore, about 87% of all air cargo shipments worldwide are international rather than domestic.

Conventional metrics for air freight (I will use air cargo and air freight interchangeably in this article) are freight tons carried; and freight ton-kilometers (or ton-miles) performed. The latter is calculated simply as product of tons carried and kilometers flown. Thus, a flight carrying ten tons of cargo over 5000 km will generate 50,000 ton-kilometers of cargo. Interestingly, cargo is recorded and reported by the airlines separately from mail carried by the aircraft. Note also that in commercial aviation the notion of freight excludes passengers' checked luggage, even if the passengers have separately paid the airline for it. Only freight accompanied by air freight airway bill and air courier shipments are counted as air cargo.

According to the International Air Transport Association (IATA), in 2018 airlines worldwide have carried 63.3 million freight tons of cargo, collecting over \$110 billion in revenue for it (total airline revenues in 2018 are estimated at \$812 billion). This makes 2018 the first year in which air cargo revenues globally exceeded \$100 billion per year (IATA, 2019).

Air cargo flows generally reflect the global economic activity. Developed European/North American nations account for about half of the total global air freight, with Asia-Pacific region (including India and China) responsible for further 36% of this industry. As the economic activity is expected to grow faster in emerging than in mature markets over the next two decades; the shares of air cargo market are forecast to adjust accordingly. Airbus forecasts Asia-Pacific and European/North American segments to represent 42% and 45% of the global air cargo market, respectively, by 2035 (Airbus, 2018).

Specifics of Air Cargo

Air cargo business is different from the commercial passenger airline business, in a number of ways. Most importantly, perhaps, unlike passengers, cargo cannot be a significant source of nonaeronautical revenue for the airports. An airport can make money off passengers buying food, drinks, and duty free; parking their cars; and using other airport facilities. Few such opportunities exist in cargo business.

On the global scale, air cargo demand tends to be considerably more volatile than passenger demand. It is also not growing as fast. Looking at the comparison between the growth in passenger and air cargo demand from 2005, as reported by IATA, two things stand out. First, cumulatively passenger demand (as measured by revenue passenger miles, or the sum of the products of passengers and distance across all the flights performed globally over a year) have increased by about 75%. At the same time, air cargo demand only grew by 25%. Second, demand for air freight has been hit much harder during the Great Recession as compared to the passenger demand, and is generally subject to more severe fluctuations.

The next difference between air cargo and passenger businesses is in the extent of competition between the airports for cargo. We know that passengers can travel to a more remote airport if the fare to their destination is considerably lower and/or if a more remote airport offers a nonstop service that is not available from the nearby gateway (see Copenhagen Economics, 2012, for an extensive discussion on this issue). The extent of such competition between airports for the passengers is subject to some debate; however, we know that competition between the airports for air freight tends to be much more intense. Freight can travel hundreds if not thousands of miles by surface transport before being transported by air.

On the other hand, airports specializing in freight transport sometimes need to be located further away from the population centers. For instance, in Europe night time flight restrictions (mostly related to local noise pollution) mean that airlines wishing to handle cargo at night will need to choose more remote airports.

Last but not least, the nature of intermodal competition is different in air cargo market. Specifically, while for some products on some markets there may be no viable alternatives to air freight transportation (e.g., flowers grown in Africa for sale in Europe); in many cases intermodal competition for air cargo is present even on long-haul markets. This can be easily contrasted to the commercial passenger air travel, where intermodal competition is typically feasible only on short-haul routes; and on long-haul routes the only viable alternative to air travel is not taking the trip in the first place.

What Goods Travel by Air

Compared to surface transportation, the key advantage of air transport is of course time. It will take weeks for a shipment to reach Europe from China by sea; whereas shipping by air is a matter of days. According to the World Bank, air freight is priced at 4-5 times the cost of road transport (if we consider weight-based pricing). The price difference between air and sea freight can be even more dramatic, with air shipments being priced at up to 16 times higher than the equivalent weight shipped by sea.

Therefore, benefits from shipping by air rather than by sea have to be sufficient to justify the extra costs involved. Consequently, goods shipped by air tend to be high-value-added and/or perishable products. Air cargo shipments are also used by the large companies worldwide to enable their just-in-time supply chains, whereby components of complex products are delivered in smaller batches when they are required in production process. This kind of supply chain is an alternative to shipping a large order to the plant, where the components are then stored for some time.

In addition to the obvious example of perishable goods traveling long distance from the place of production to where they are sold (such as flowers grown in Africa traveling to Europe or asparagus shipped from Latin America to the United States); the following industries tend to be heavy users of air freight services.

- Consumer electronics, and other high-tech goods. Most likely, your smartphone or laptop has been flown from where it was manufactured to where you bought it. These products, in addition to being a classical example of high value-added goods, tend to be compact, and can therefore be shipped by air at a reasonable cost relative to their sale price.
- Pharmaceutical industry. This is yet another classical example of high value-added and mostly compact products (some of which are also perishable).
- Fashion industry. Certainly, some products here are sold at high margins. However, even lower margin (so-called "fast fashion") brands tend to ship their products by air rather than surface transport. The following factors play a role in this decision. First, air shipment allows the products to arrive in better condition, as air freight provides for better humidity and dust control while the goods are in transit. Second, air shipments allow the companies operating stores worldwide to better control their inventory (the same goods, produced in Bangladesh, can appear in both American, Japanese, Middle Eastern, and European stores at the same time), and quickly respond to changes in consumer demand.
- Auto and aircraft manufacturing industries. These industries are increasingly using complex just-in-time supply chains, enabled by air freight.

As an example, the German Federal Statistical Office reported that in 2017, 61% of electronic and optical goods (by value) exported from Germany were shipped to their destination countries by air. The corresponding figure for the pharmaceutical and chemical industry was 25%; and for the vehicle, aircraft, and ship manufacturing it was 14%.

Air Cargo Airline Business Models

The following key facts about the air cargo market are of note:

- On the global scale, about half of air cargo by volume is shipped by freighter aircraft. The other half of air freight travels in the belly of commercial passenger flights, generating additional revenue for the airlines.
- Air cargo market tends to be more fragmented than the passenger market—there are many more small-scale cargo airlines than small passenger carriers in operation.
- There are three air cargo business models currently in operation, broadly speaking.

According to Boeing's estimates, over the next 20 years or so we can expect the share of cargo carried by full freighter aircraft to decrease to about 37% from the current 50-50 split ([Boeing, 2019](#)). This of course does not mean that there will be fewer cargo planes in the airlines' fleet—both full freighter and belly cargo segments will be growing, but the latter will increase at a faster rate than the former. This expected trend can be explained by the following factors. First, the airlines' fleet will generally continue growing. Second, passenger carriers, facing steep competition and considerable aircraft ownership costs, will continue looking for ways to increase revenue from their aircraft, and belly cargo is exactly one of such ways. This will be facilitated by the modern information

technology, which will simplify the logistics related to the belly cargo. Third, continued liberalization of international aviation will make it easier for the airlines operating on international routes to adopt new business approaches.

The cargo aircraft fleet consists of purpose-built cargo planes, and the converted cargo aircraft. A number of passenger planes find their second careers as cargo aircraft. The largest purpose-built cargo aircraft currently in service is Antonov-225 Mriya (Ukrainian for "the Dream"). Designed by Antonov Design Bureau and built in 1985 in Kyiv, the single plane of this type is operated by the Ukrainian company Antonov Airlines. Mriya's maximum take-off weight is 640 tons, which is about 17% more than the same figure for Airbus A380—the largest commercial passenger jet built to date.

Both Airbus and Boeing manufacture purpose-built cargo planes, on their popular passenger platforms. One can say that iconic Boeing-747 aircraft found its new life in freight transport: while the manufacturer stopped making the passenger version of the plane, and the airlines are phasing them out of their fleet; the freighter version of the newest 747-8 plane is still in production. A number of combi passenger-cargo airplanes have also been built over the years. These planes feature partition of the cabin into passenger and cargo compartments. A number of air carriers have historically operated combi planes. At present time, however, these aircraft are not very popular, and many of those remaining in operation have been converted for either all-passenger or all-cargo use.

Airbus estimates that by 2035 global fleet of freighter aircraft will number about 3000, nearly double from the current figure. Interestingly, the manufacturer projects that about two-thirds of the new freighter planes (1860) will be conversions from the passenger fleet. The remaining third of new freighters (870 according to Airbus estimates) will be factory-built new planes.

Belly cargo transportation (where the freight is carried in the belly of a passenger jet operating its scheduled flight) has increasingly gained popularity in the age of higher oil prices and fiercer competition between the airlines. Many carriers realized the revenue potential of the space below the passenger deck, which otherwise remains empty on a flight that is operating anyway. This means that belly cargo can in principle be priced at the marginal cost—this cargo only needs to pay for the additional fuel and other costs, whereas in a dedicated freighter aircraft cargo must pay for the entire cost of the flight. With wide-body aircraft being produced at record rates, a lot of belly cargo capacity is added to the aviation system. For instance, Boeing's wide-body 777 aircraft, in its 777-300ER modification, has belly cargo capacity of 202 m³, or approximately six standard 20-foot containers used in sea shipping. By contract, cargo capacity of the Boeing-777 freighter is about 630 m³, or 19 standard 20-foot containers.

We can generally speak about three business models employed by the airlines carrying cargo (Morrell and Klein, 2018). First, traditional network carriers offer cargo transportation as one of their services, in addition to the passenger transportation. These airlines transport cargo both in the belly of their passenger flights, and by full freighter aircraft. Sometimes cargo is transferred at the airline's hub between passenger and full freighter flights. The "traditional" airlines differ in terms of how they incorporate air cargo into their business models. Some carriers have dedicated freight divisions or subsidiaries that operate a fleet of full freighter aircraft (e.g., Emirates Sky Cargo, or Martinair-cargo airline owned by Air France-KLM). Other airlines focus solely on belly cargo—for instance, the three major US network carriers (American, United, and Delta) do not have full freighters in their fleet, but they accept shipments for transportation in bellies of their scheduled passenger services. These shipments are handled by the airlines' cargo divisions. Many of the low-cost carriers, such as Ryanair-Europe's largest airline in this class—stay away from air cargo business altogether.

The second air cargo business model is the freight integrator company. In this category, we have such recognizable companies as FedEx, UPS, and DHL. As the term "integrator" suggests, these companies arrange the shipment from start to finish, using the assets that they own. When you ship something via, say, FedEx, your parcel is usually dropped off at a FedEx facility. Then it is loaded onto a FedEx truck, which delivers it to a FedEx sorting facility, from where it may be loaded onto a FedEx aircraft (and could be transferred from one FedEx aircraft to the next at one of the company's hubs). Once the shipment arrives to the FedEx sorting facility at the other end of the journey, it is then again loaded onto a FedEx truck, and the final delivery to the door is made by FedEx as well. On some "thinner" markets (i.e., more remote origins or destinations) the first and/or last steps might be performed by local delivery companies working on a contract with FedEx. Integrators tend to focus on the smaller parcel segment of the cargo industry, specializing in express delivery. These companies tend to be large, as scale here is required to achieve global coverage and efficiency of operations. In fact, FedEx and UPS are the largest and third largest air cargo carriers in the world, respectively, as measured by freight-kilometers flown (the second being Emirates Sky Cargo).

Last but not least, most of the cargo airlines follow what is known as the freight forwarder business model. These airlines own (or lease) their aircraft and fly cargo around the world; however, the freight comes to them from third parties (oftentimes transportation is arranged via agents, and forwarding airlines deal with the handling agents rather than directly with the customers shipping the freight). These airlines tend to be mid-sized or small, and only have full freighter aircraft in their fleet. The largest freight forwarded airline in the world by freight-kilometres flown is Luxembourg-based Cargolux, which flies cargo around the world using its fleet of over 20 Boeing 747-8 freighters. Cargolux is at the bottom of top 10 cargo carriers in the world, as measured by freight-kilometers flown. One peculiarity of business models these carriers tend to follow is that their routes and schedules are generally different from those of passenger and cargo network carriers. Rather than operating in a familiar hub-and-spoke pattern, whereby an aircraft leaves the airline's hub, reaches its destination, and returns to the hub; freight forwarders tend to operate multi-stop routes, which sometimes take the aircraft around the world before it returns to its home base.

Of the top ten cargo airlines in the world, two are integrators (FedEx and UPS, as noted above), one is a freight forwarder (Cargolux), and remaining seven are cargo divisions or subsidiaries of passenger network carriers. Interestingly, in the latter category six out of seven carriers are based in the Middle East or Far East, with Lufthansa Cargo being the only European cargo subsidiary of a passenger airline to make this top-ten list.

Table 1 Top-20 cargo and passenger airports worldwide, 2009-18

Airport	Position in top-20 list by cargo volume		Position in top-20 list by passenger traffic	
	2010	2018	2010	2018
Hong Kong	1	1	11	8
Memphis	2	2	-	-
Shanghai Pudong	3	3	20	9
Seoul Incheon	4	4	-	16
Anchorage	5	5	-	-
Dubai	8	6	13	3
Louisville, Kentucky	7	7	-	-
Taipei	14	8	-	-
Tokyo Narita	9	9	-	-
Los Angeles	13	10	6	4
Doha	-	11	-	-
Singapore Changi	11	12	18	19
Frankfurt	6	13	9	14
Paris Charles de Gaulle	7	14	7	10
Miami	12	15	-	-
Beijing Capital	16	16	2	2
Guangzhou	-	17	19	13
Chicago O'Hare	18	18	3	6
London Heathrow	15	19	4	7
Amsterdam Schiphol	17	20	15	11
Atlanta	-	-	1	1
Tokyo Haneda	-	-	5	5
New Delhi	-	-	-	12
Dallas-Ft Worth	-	-	8	15
Jakarta	-	-	16	18
Denver	-	-	10	20
New York JFK	19	-	14	-
Bangkok Suvarnabhumi	20	-	17	-
Istanbul Ataturk	-	-	-	17
Madrid	-	-	12	-

This list has been compiled based on the data from Airports Council International (ACI).

Naturally, the three business models described above represent "pure types" of ways cargo airlines arrange their business. In reality, many carriers operate more or less hybrid models.

Key Cargo Airports

If we compare the lists of top 20 passenger and cargo airports in 2018 by volume of traffic handled (number of passengers and tons of cargo, respectively), we will see the following discrepancies:

- Top five lists of airports by passenger and cargo traffic are entirely different. None of the top five passenger airports makes the list of top five air cargo gateways, and vice versa.
- Only three of the top 10 passenger airports are in the corresponding list of top cargo airports. These airports are Hong Kong (number eight by passenger traffic and top cargo airport), Shanghai Pudong (number nine by passenger traffic and number three by cargo volume), and Los Angeles (number four by passenger traffic, number ten by cargo).
- Three US airports in the top 10 cargo list (Memphis, Anchorage, and Louisville, Kentucky) are not even in the list of top-50 passenger airports worldwide.
- Of the top-20 cargo airports, ten are in the Middle East and Asia, six are in the USA, and four are in Europe.

Most of the top cargo airports gain their position by being either key regional gateways (Hong Kong, Seoul Incheon, Tokyo Narita, Miami), key hubs (Singapore, Dubai, Doha, Anchorage), or both (Frankfurt, Chicago O'Hare). Two largest US cargo airports (Memphis and Louisville) gained their position by being hubs of the largest cargo integrators (FedEx and UPS, respectively).

Interestingly, top cargo airports in different regions tend to be driven by different kinds of cargo airline business models. In the USA, three of the four cargo airports in the global top-20 are hubs of the integrator carriers. The top Middle Eastern cargo airports are

also hubs of the network carriers based in the region. The key cargo airports in China (as well as Hong Kong and Taipei) are the main gateways for the region's trade with the world.

Volatility of demand for air cargo is known to be higher than that for passenger travel. Despite this, the list of top-20 cargo airports has remained rather stable over the last 10 years. Out of 20 airports in this list in 2010, 18 are still in it in 2018. The same is true for the list of top-20 passenger airports. If anything, there has been more movement in the top-10 list of airports by passenger volume as compared to the same list for cargo airports. **Table 1** illustrates this point.

Concluding Remarks

Air cargo industry is a dynamic and complex business. In 2018, air cargo revenues have exceeded \$100 billion mark for the first time in history. This means that in revenue terms cargo constitutes about 12% of the airline industry globally. Air cargo business plays an indispensable role in enabling both international trade and the global supply chains. According to Boeing, about 35% of internationally traded goods by value travel by air.

Compared to the passenger airline business, the air cargo industry is more competitive and volatile. In addition to competition between the airlines, intermodal competition for air cargo is often present even on long-haul routes. Competition for air cargo between the airports is also said to be quite keen, as freight forwarders use surface transport to move cargo for hundreds or thousands of miles from the point of shipment origin before it is loaded onto an aircraft.

Air cargo is used to ship a variety of products. Most products shipped by air are high-value-added or perishable. However, some industries use air cargo to ship less than high-value-added products for logistics reasons, such as enabling just-in-time supply chains.

Air cargo is travels in both full freighters and the belly of passenger airliners. Currently, there is about 50-50 split between these two modes, but the share of belly cargo is projected to increase in the future as more wide-body aircraft capacity becomes available, fierce competition between passenger airlines incentivises the carriers to look for additional revenue sources, and information technology enables the relevant logistics. The COVID-19 crisis may change the structure of the air cargo industry. At the time of this writing, the future of the commercial aviation remains subject to much speculation. However, most analysts believe that the industry will eventually return to its growth path. Air cargo demand has remained robust throughout the crisis, with some airlines temporarily transforming their passenger aircraft for cargo use.

Intermediaries (cargo handling agents) play a more important role in air cargo business as compared to the passenger side of airline industry. In the air passenger business, travel agent's role is often limited to selling the tickets. Whereas cargo handling agents are closely involved with handling the goods being shipped. Freight integrator companies essentially integrate freight forwarding agents into their structure, dealing with shipments door-to-door. Unlike in the passenger business, where the airlines are trying to divert bookings from the agents to their own channel; the role of the agents in the cargo business will likely persist.

Introduction

Air transport is a technological marvel that has experienced an astonishing rate of progress. From the Wright Brothers' initial heavier-than-air powered flight in 1903 to the introduction of jumbo jet aircraft in the 1960s and global networks of airliners in the 2000s, commercial air transport has come a long way in a relatively short period of time. An important part of the story behind this progress has been the role of commercial airline regulation which created an operating environment that allowed air transport to grow into a successful and indispensable component of global transportation and continues to facilitate its development.

This article will highlight the significance of airline regulation by first discussing its importance as part of the historical evolution of commercial air transport. Concerns with safety, national security, and economic stability were the principal justifications for instituting airline regulations historically, and continue to be important aspects of regulation today. Both safety and economic stability have improved greatly since the early years of commercial air transport, due to technological advancements but also to the role of regulation in mandating safer operations and in creation of a more stable industry. Yet both safety and economic stability remain important considerations, and underscore the need for continued vigilance from national and international regulatory agencies. Concerns with air transport security have grown over time due to the rise of terrorism, while other issues such as environmental impacts (especially greenhouse gas emissions), consumer protection, and health have been added more recently to the regulatory agenda. Recent developments in each of these areas will be discussed.

This paper is organized as follows: Section 1 provides some historical background to airline regulation while Section 2 discusses contemporary issues including aviation security, safety, consumer protection, environmental impacts, and health, followed by a brief summary and conclusions.

Historical Background

Commercial air transport began with the establishment of air mail and limited passenger services in the U.S. and several European countries in the late 1910s and 1920s. The expansion of aviation technology developed rapidly as a result of its application to military purposes during World War I. The U.S. Post Office began air mail service between Washington and New York in 1918, and the U.S. Contract Air Mail Act of 1925 (also known as the Kelly Act) transferred air mail and early passenger service to private sector companies by way of competitive bids. The first regularly scheduled daily international air passenger service had commenced in 1919 between London and Paris. This led to the need to establish some initial national security regulations for international air service, codified by the Paris Convention of 1919. The signatories to this agreement recognized not only the "complete and exclusive sovereignty" of states to the air space above their territories, but also the "freedom of innocent passage" through the airspace of other contracting states (Budd, 2014; Goetz, 2017) (see also articles 10425 The history of air transport, 10426 The geography of air transport, and 10428 Air transport and its territorial implications).

Because aeronautical technology was still in a developmental stage, early aviation was beset by numerous aircraft accidents, fatalities and injuries. As an example, pilots for the U.S. Post Office air mail service had an average life expectancy of only 4 years; 31 of the first 40 pilots were killed in action (Perrow, 1984). In response, the U.S. created safety standards and a regulatory framework through the Air Commerce Act of 1926 that vested jurisdiction over safety and the maintenance of navigation facilities and communication networks to the Aeronautics Branch of the Department of Commerce. It introduced initial regulations involving aircraft registrations, pilot certifications, and aircraft traffic safety rules. The US pioneered air navigation through the development of

lighted airways using high-intensity beacons to guide pilots along prescribed routes at night, as well as a national system of airfields. These and other supportive activities underscore a well-recognized principle that “ninety percent of aviation is on the ground” (Davies, 2011: 7). Similar regulations and safety measures were instituted in other countries with newly developing airline services.

Economic regulation of airlines became a more pressing concern with the onset of the Great Depression in the 1930s. Concerns about the economic viability of the fledgling private sector airline industry in the U.S. led to the Civil Aeronautics Act of 1938 (The Civil Aeronautics Act also transferred safety regulation from the Bureau of Air Commerce (formerly Aeronautics Branch) to the Civil Aeronautics Authority. In 1940, President Roosevelt split the Civil Aeronautics Authority into the Civil Aeronautics Administration (for air traffic control, pilot and aircraft certification, safety enforcement, and airway development) and the Civil Aeronautics Board (for economic regulation and some safety regulation, including accident investigations)) that vested the newly-created Civil Aeronautics Authority (later the Civil Aeronautics Board) with the power to control entry and exit of carriers (both interstate and foreign commerce) on new or existing routes, regulate fares, award subsidies, control mergers and intercarrier agreements, and investigate deceptive trade practices and unfair methods of competition. This type of economic regulation was similar to what had been established for the U.S. railroad industry through the creation of the Interstate Commerce Commission in 1887 to limit the monopoly power of railroads through regulation over pricing, entry, exit, mergers, and acquisitions (see also article 10078: Regulation and Competition in Railways). Economic and/or antitrust regulation was extended to airlines, motor carriers, telephone, banking, steel, petroleum, and electric power in the U.S. during the 1880s–1930s period because these industries possessed characteristics of public utilities subject to monopoly or oligopoly control and served as important “public interest” industries (Goetz, 2017). In a newly emerging industry, such as the airline industry of the 1930s, government regulation of private carriers was considered a necessity to avoid the “destructive competition” that would have been deleterious to economic stability and the longer-term viability of a key industry with national security implications. In other countries, airlines were already either state-owned or were awarded exclusive franchises as “chosen instruments” to develop air service as national “flag” carriers, so regulatory oversight was already embedded in the institutional structure of these industries.

Aviation technology advanced greatly as a result of military applications during World War II which laid the groundwork for a massive expansion in the postwar period. Anticipating the need to organize the postwar commercial aviation environment, representatives from 52 states met in Chicago in 1944 to create a new international regulatory framework. The Chicago Convention of 1944 recognized the so-called “five freedoms” of the air, thus leading to a framework which individual states could use to negotiate air service agreements. While the first two freedoms (right to fly over territory of another country and right to land for refueling and maintenance) were derived from the 1919 Paris Convention, the third and fourth freedoms refer to the right to transport passengers or cargo between the home country and a foreign country, while the fifth freedom refers to carrying passengers or freight between two foreign countries by a flight that originates in the home country. The United States was eager to pursue a more open multilateral regime that would allow all five freedoms for all signatory states. European nations, most notably the United Kingdom, preferred a more restrictive approach that would require negotiated bilateral agreements concerning the relative amount of air service provided between two countries based on the principle of reciprocity. The ensuing Bermuda I bilateral air service agreement in 1946 between the US and the UK included which city-pairs could be served, the specific airlines designated to provide service, as well as rules concerning capacity levels, fares, and freight rates, and became the basis for other international bilateral agreements (Bowen, 2010; Debbage, 2014). The International Air Transport Association (IATA) was established in 1945 as the fare-setting and global trade organization for the international airline industry, while the International Civil Aviation Organization (ICAO) was founded in 1947 as an agency of the United Nations principally concerned with rules and procedures of international air navigation. The Chicago Convention and the formation of IATA and ICAO set the stage for postwar commercial air transport expansion (Goetz, 2017).

Commercial air transport expanded greatly in the 1950s and 1960s with the onset of the “jet age.” Concerns over safety, however, continued as a result of a number of major air accidents. The first commercial passenger jet, the British-built de Havilland Comet 1, was entered into service in 1952, but was grounded in 1954 due to several high-profile accidents caused by the previously unknown problem of “metal fatigue.” A mid-air collision over the Grand Canyon in the U.S. in 1956 uncovered problems with communication and air traffic control systems. These and other accidents led to additional safety regulations and procedures, and in the U.S., the passage of the Federal Aviation Act of 1958 that increased funding for airline safety and transferred most safety responsibilities and air traffic control to a newly-created Federal Aviation Agency (later renamed the Federal Aviation Administration [FAA]). Authority over aircraft accident investigations was transferred from the CAB to the National Transportation Safety Board (NTSB), a new independent agency.

By the 1970s, several economic studies (Caves 1962; Cherrington 1958; Douglas and Miller 1974; Jordan 1970) had begun to question the desirability of continued economic regulation in the U.S. airline industry. It was felt that the airline industry had become more mature and competitively balanced since its early development in the 1930s, and that by removing regulatory control from the Civil Aeronautics Board (CAB), markets would operate more efficiently and carriers could offer consumers a wider range of price/service options. Competition would flourish and contribute to enhanced economic productivity. After more studies and much policy debate, the US promulgated the Airline Deregulation Act of 1978 which allowed US airlines to make decisions on entry, exit, and fares, and transferred authority over mergers to the US Department of Justice upon termination of the CAB in 1985 (Goetz, 2017) (see also article 10075: Privatization and deregulation of the airline industry).

At the same time, the US also adopted an “open skies” policy for international air service and, as part of a wider neoliberal policy agenda, encouraged other countries to follow suit. The European Union liberalized its air transport industry in a succession of three packages in 1987, 1990, and 1993 with full liberalization starting in 1997. Privatization and liberalization policies were adapted to

varying degrees in Asia, Latin America, the Middle East, and Africa. What ensued was a change in the market structure of the airline industry around the world whereby many state-owned airlines were privatized, many new entrants including low-cost carriers started airline service, mergers resulted in a smaller number of very large airlines, and global strategic alliances created mega-airline groupings.

It has been over 40 years since the US deregulated its airline industry, and studies have found US deregulation to be successful in lowering average fares, providing more flights, increasing carrier efficiency, and encouraging new entrant competition, while maintaining a good safety record (Transportation Research Board, 1991, 1999; US Department of Transportation, 2000; US Government Accountability Office, 2006; Morrison and Winston, 2008). On the negative side, many airlines have encountered wide swings in profitability, with losses being much larger than gains. This financial turbulence has resulted in increasing instability in industry structure and employment, while service quality has declined. Fares and service for smaller cities, shorter-haul routes, and more concentrated markets (where single-carrier domination persists) have also been negatively affected (Goetz and Vowles, 2009). Deregulation and liberalization have also led to increased concerns about labor relations and consumer protection as a result of increased power and control exercised by the airline companies (see also article 10606 Transport Policy and Planning: Air Transport).

Major Issues in Contemporary Airline Regulation

Aviation Security

Among the issues of most concern to airline regulators today is security. Concerns with aviation security date back to the 1960s and 1970s when airline hijackings became a problematic trend followed by an increasing number of terrorist incidents on airlines, including the infamous September 11, 2001 attacks in the US. Because of its high-profile role in the global economy and the symbolic importance of national flag carriers, air transport has become a target for terrorists thus necessitating increased security regulations and more technologically enhanced security systems.

Prior to the 1960s, aircraft hijackings and other criminal incidents were relatively rare, so security regulations were minimal. Hijackings increased in the 1960s involving persons attempting to escape from persecutors and/or to seek asylum, most notably on flights to and from Cuba. Responses to airline hijackings in the 1960s included regulations prohibiting weapons onboard and refusing to transport threatening passengers, as well as the introduction of trained air marshals on random flights. The Tokyo Convention, an international treaty signed in 1963 and effective from 1969, specified that the state in which an aircraft is registered has jurisdiction over crimes committed onboard, and that countries in which a hijacked airliner lands have an obligation to allow the crew and passengers to continue their journey and for the aircraft to be returned to its owner. The Hague Convention of 1970 enabled states to prosecute hijackers from other countries and to deprive them from asylum (Dempsey and Gesell, 1997).

Despite these efforts, civil aviation became an increasingly recognized target of international terrorism from the late 1960s onward. In 1968, terrorists from the Popular Front for the Liberation of Palestine hijacked an Israeli aircraft and held its passengers hostage, which led to more terrorist incidents (Enerstvedt 2017). In response, the Convention for the Suppression of Unlawful Acts against the Safety of Civil Aviation, also known as the Sabotage Convention or the Montreal Convention, was signed in 1971 and called for signatory states to prohibit and punish behavior such as acts of violence onboard an aircraft and destroying or damaging aircraft. Aided by reports and initiatives from ICAO in the 1970s, security at airports was increased through greater electronic surveillance, rudimentary passenger and baggage screening, and information sharing among national security agencies. The US FAA emphasized a “layered” system of defense including intelligence, pre-screening and checkpoint screening (contracted to private security companies), and onboard security.

By the 1980s, while the number of airline hijackings declined, terrorist bombings and sabotage started to increase, including Air India Flight 182 in 1985 which killed 329 people, and Pan Am Flight 103 in 1988 that resulted in 270 deaths. The number of aircraft hijackings increased again in the 1990s, most notably in China and East Asia, as well as in Europe. Additional security measures, such as manual searches, use of metal detectors, and passenger interviewing and profiling were implemented in many countries.

The September 11, 2001 (9/11) terrorist attacks in the United States involved hijacking of four airliners by 19 Al-Qaeda terrorists, and the use of these airliners as weapons to destroy the World Trade Center in New York City, and damage the Pentagon building in Washington DC. Altogether 2996 people died in these attacks, the deadliest aviation terrorist incident in history. The 9/11 attacks represent a critical watershed moment in national and aviation security when the threat level dramatically increased, and new regulations and countermeasures were enacted in the US and throughout the world. In the wake of 9/11, the US Transportation Security Administration (TSA) was created and given authority over all US aviation security, including enhanced passenger and baggage screening, federal air marshalls, explosive detection, and other airport and airline security activities. The TSA introduced numerous regulations and procedures, such as: (1) more stringent traveler identification requirements including no-fly lists and passenger personal data transfer, (2) more intrusive passenger and baggage screening involving explosive trace detection, X-ray and backscatter X-ray machines, CTX machines, canine units, camera surveillance, full-body scans and physical pat-downs, (3) restrictions for carry-on baggage including volume limits on liquids and gels and prohibitions on a range of other items that could be used as weapons, and (4) restricted access to gates and terminals only for ticketed and screened passengers and employees. ICAO adopted resolutions that called for locking cockpit and flight deck doors, sharing of threat information between national aviation security

agencies, and instituting a comprehensive aviation security audit program (Enerstvedt, 2017) (see also article 10104 Airport Security and article 10432 Airport Regulation).

While the number and severity of aviation terrorist incidents declined after 9/11 due in part to the enhanced security regulations and procedures, terrorist attacks have continued in different places and settings. In 2015, for example, an inflight explosion on a Russian passenger aircraft departing Egypt resulted in 224 deaths, and was attributed to ISIL terrorists.

Safety

During the early years of aviation as a newly developing technology, regulations were enacted to ensure safe operations of civilian aircraft. While the safety of commercial air transport has improved greatly since those early years, the need for safety regulation continues nevertheless as new technologies and equipment require vigilance on the part of ICAO and national aviation safety agencies. ICAO (2019d) considers safety to be at the core of their fundamental objectives. ICAO continues to develop and maintain standards, recommend practices and procedures for air navigation services, and develop global strategies to improve safety (see also article 10113 Aviation Safety–Commercial Airlines).

Two recent accidents involving the Boeing 737-MAX aircraft highlight the need for continued safety regulation. In October 2018, a Lion Air flight crashed shortly after takeoff resulting in 189 fatalities, and in March 2019, an Ethiopian Airlines flight also crashed shortly after takeoff, resulting in 157 deaths. In response, ICAO, the US FAA, and other national aviation safety agencies grounded the 737 MAX aircraft until further notice. The US Department of Transportation has requested an audit of the regulatory process that allowed the aircraft to be certified for airworthiness in 2017. As of this writing, the 737 MAX has not yet been cleared to resume flight operations.

The introduction of unmanned aerial vehicles (UAVs), also known as drones, presents additional aviation safety challenges. Drones were first used in military applications, but have been used increasingly in civilian applications, including aerial photography, data collection, delivery of goods, and by recreational hobbyists. The expanding use of drones has required aviation regulatory agencies to establish safety guidelines related to their use. As part of its Next Generation Air Transportation System (NextGen), the US FAA is developing regulations and procedures to accommodate the increased demand for drone use while ensuring safe operations of all aircraft. A special airworthiness certificate is required for drone operation, and an automated sense-and-avoid system will be required for drones to be certified as part of the NextGen system. There are also significant security and privacy issues associated with the introduction of drones (ALTawy and Youssef 2016).

Consumer Protection

In the wake of economic deregulation and liberalization across the airline industry, concerns about consumer protection have grown. As airlines have amassed more market power and operational control, some of their policies and practices have worked to the disadvantage of consumers. Issues such as overbooking flights and bumping passengers, tarmac delays and flight cancellations, false and misleading advertising, lost or damaged baggage, reductions in seat pitch and width, and transparency in pricing and ancillary fees have caused airline passengers to seek redress through enhanced consumer protection regulations, such as the proposed Airline Passengers' Bill of Rights in the US (Correia and Rouissi, 2015; US Congress, 2017).

Tarmac delays have been especially noteworthy. From May to September 2009 in the US, there were 535 instances of fully-loaded passenger aircraft delayed on airport tarmacs for more than three hours. In some extreme cases, passengers were kept on planes anywhere from 6 to 12 h without access to the airport terminal. In 2010, the US Department of Transportation issued a regulation that passenger-laden aircraft cannot idle on the tarmac for more than 3 h or the airline will be fined. This regulation resulted in a drastic reduction in long tarmac delays (Potter, 2017).

Environmental Impacts

As a mode of transport, aviation possesses many advantages, especially its ability to cross land or water at a higher speed of travel than any other commercial mode. But air transport also creates significant negative environmental impacts, especially in terms of noise, local air pollution, and global greenhouse gas emissions (see also article 10720 Environmental Issues of Airports and Aviation).

Noise has been recognized as a problem in commercial aviation since at least the 1960s. The US FAA issued noise standards in 1969, which were enhanced by the Noise Pollution and Abatement Act of 1970 and the Noise Control Act of 1972. Noise standards were amended in 1977 that created three stages of aircraft based on noise emission levels, together with plans for systematically phasing out the noisiest aircraft. The US Aviation Safety and Noise Abatement Act of 1979 provided assistance to airport operators to create noise compatibility programs and noise exposure maps for the purpose of reducing noise impacts. Regulations restricted noise-sensitive land uses, such as residences, schools, and hospitals, in airport areas (Ward et al., 2010). The US Airport Noise and Capacity Act of 1990 required that airlines phase out Stage 2 aircraft by 2000, while the European Union adopted a similar program phasing out noisy aircraft (Dempsey and Gesell, 1997). ICAO (2019c) and other national agencies have also created noise standards and developed programs to reduce noise exposure through reduction of noise at the source, land use planning and management, noise abatement operational procedures, and operating restrictions (see also article 10723 Noise Pollution from Transport and article 10731 Transport Noise and Health).

Because aircraft are powered by engines that utilize petroleum as their main fuel source, and because air transport activity continues to increase, air pollution emissions that directly affect human health are a growing concern. The principal pollutants that impact local areas near airports include nitrogen oxides (NO_x), carbon monoxide (CO), and non-methane volatile organic compounds (NMVOCs) (Upham et al., 2003). These and other pollutants were targeted in the U.S. Clean Air Act Amendments of 1970 through the establishment of National Ambient Air Quality Standards (NAAQS) to monitor and assess their emission levels. The US Environmental Protection Agency (EPA) and FAA established aircraft production standards to limit emissions of these pollutants (Dempsey and Gesell, 1997). ICAO also established engine emission certification requirements for these pollutants (Upham et al., 2003). Airport-related ground transportation contributes to local air pollution mainly through emissions from internal combustion engine motor vehicles. Many countries and cities have established standards and regulations that seek to control levels of pollutant emissions in airport areas (see also article 10712 Transportation Contribution to Air Quality).

Air transport is a contributor to global atmospheric emissions, most notably greenhouse gases such as carbon dioxide (CO₂). The Intergovernmental Panel on Climate Change (IPCC) has estimated that aviation emissions of CO₂ are 2–3% of total global greenhouse emissions, but that the amount of CO₂ emissions from aviation is expected to grow around 3–4% per year (ICAO 2019b). The Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA), the EU Emissions Trading Scheme (EU ETS) for air transport, and others in New Zealand, South Korea, and China are aimed at limiting air transport's CO₂ emissions (Scheelhaase 2019). The Paris Agreement of 2016 as part of the United Nations Framework Convention on Climate Change (UNFCCC) calls for signatory countries to reduce GHG emissions so as to limit temperature increase to 1.5°C above pre-industrial levels. Many countries have made individual carbon reduction commitments, such as the UK with a target of 80% reduction from 1990 levels by 2050 (Palling et al., 2014). As a UN agency, ICAO (2019a) supports initiatives aimed at reducing GHG emissions from aviation including coordination of and assistance for state action planning on CO₂ emission reduction activities (see also article 10620 Climate Change and Transport Policy and article 10713 Transportation Contribution to Greenhouse Gases).

The IPCC (1999) has found that other aircraft emissions such as nitrogen oxides (NO_x), methane (CH₄), sulfur oxides (SO_x), water vapor, as well as contrail and cirrus cloud formation, also contribute to climate change especially in the upper atmosphere (Palling et al., 2014). Lee et al (2009) assessed aviation's CO₂ and non-CO₂ contribution to total radiative forcing to be 4.9%, with CO₂ accounting for 1.6% and non-CO₂ emissions at 3.3%. The EU Council is considering how to integrate regulation of non-CO₂ emissions into its existing EU-Emission Trading Scheme (Scheelhaase, 2019).

Health

Air transport has facilitated unprecedented levels of intercontinental travel, thus contributing to globalization and increasing economic and social interaction. While these trends have resulted in many positive effects, one concern has been increased risk of rapidly spreading communicable diseases and viruses that can affect human health. An outbreak of Severe Acute Respiratory Syndrome (SARS) in Asia in 2003 spread to other cities via air transport passengers, and this outbreak was implicated in declining levels of air passenger traffic that year. In 2009–10, an outbreak of the H1N1 flu virus led to the European Union health commission warning that nonessential travel to the US or Mexico should be postponed. More recently, outbreaks of the Ebola virus in Africa in 2014 and the Coronavirus (Covid-19) in China and throughout the world in 2020 have raised alarms for international air travel. Due to coronavirus-related restrictions on air travel starting in January 2020, worldwide air passenger travel declined precipitously resulting in over 90% reductions in year-over-year passenger totals during the first half of 2020. The World Health Organization (WHO) in coordination with ICAO has established regulations and procedures to limit the spread of communicable diseases including the provision of accurate and timely information to all persons involved in international air travel. Furthermore, ongoing health concerns related to the enclosed aircraft cabin environment, especially exposure to recirculated air on long flights, have prompted the WHO and international aviation agencies to issue guidelines for reducing risk of airborne illness transmission (see also article 10701 Sustainable Development Goals and Health and article 10708 Planetary Health).

Summary and Conclusion

Airline regulation continues to be an important activity of national and international aviation agencies to ensure well-functioning air transportation systems. While the historical focus of airline regulation has been on safety and economic stability, more recent challenges in aviation security, environmental impacts, consumer protection, and health have expanded the regulatory gaze to include these and other issues as well (see also article 10427 The future of air transport).

Introduction and Definitions

Air vehicles—aircraft—are fundamentally conceived and built as transportation means, for civil and commercial use, for military and special applications, as well as experimental purposes. The aim of this article is to present and discuss the general, widely renowned, classification of aircraft largely employed for civil and/or commercial transportation, for both civil passengers and cargo.

Table 1 Air vehicles classification.

	Type of lift force	Lifting devices		Nomenclature
Aerostats (Lighter-than-air)	Static lift	Lifting envelopes with lighter-than-air gas	with propulsion system	Airships
			without propulsion system	Free balloons, kite balloons
Aerodynes (Heavier-than-air)	Aerodynamic lift	Fixed wing surfaces	with propulsion system	Aircraft, Seaplanes, Amphibious, UAS
			without propulsion system	Gliders, Tethered flying cerfs
		Mobile wing surfaces	Rotary wings (rotorcraft)	Helicopters, Autogyros, Quadrotors (quadcopters)
	Flapping wings		Ornithopters	
		Direct reaction (reaction engines)	Directed/steerable jet thrust (turbojets, rockets)	
	Mixed lift	Rotary/Fixed wing surfaces + directed lift jets		VTOL, STOL aircraft, Convertiplanes (Tiltrotor)

Air vehicles are transportation means able at moving through the airflow deriving their lift—the sustaining force in flight—by fundamentally two distinct sustaining phenomena: static lift or dynamic lift (Losito, 1982). Hence, all air vehicles, lighter-than-air and heavier-than-air, can be classified in the following two primary categories:

1. Aerostats: lighter-than-air aircraft with static sustaining force, where the lift is produced by Archimede's physical law (no relative motion body-airflow);
2. Aerodynes: heavier-than-air aircraft with dynamic sustaining force, where the lift is produced by means of the known Newton's law of dynamics (relative motion body-airflow).

Based on these two primary categories, a general, exhaustive classification of air vehicles is reported in **Table 1**. It has to be specified that, due to limitations in terms of space given for this editorial contribution, the categories of aircraft not purely associated with civil transportation, namely: military aircraft, Unmanned Air Systems (UAS), Remotely-Piloted Aircraft Systems (RPAS), drones, quadrotors, flapping-wing devices, direct-reaction aerodynes (missiles), and mixed-lift aircraft (VTOL/STOL, convertiplanes) reported in **Table 1** for completeness, will not be herein discussed. Notwithstanding, a complete list of additional sources in the section "Further reading" is provided for further investigations and details on these nomenclature and topics.

This paper is structured as follows: First section describes the first type of air vehicles, those which are lighter-than-air, called aerostats; Next section presents and describes air vehicles which are categorized as heavier-than-air, the larger category in the aeronautics nomenclature; Further section describes air vehicles conceived with aerodynamic lift devices; and the last section presents air vehicles categories classified by aircraft types and specific roles.

Lighter-Than-Air Aircraft (Aerostats)

Aerostats are classified into three main categories:

- Free balloons, having a spherical (hot-air balloon) or non-spherical shape, are not anchored to the ground so that they are free to move in the air and they are not equipped with a propulsion system. The uplift for a free balloon is given by hot air, provided by burners in a cabin attached with iron cables and karabiners to the balloon or by a lighter-than-air gas such as helium or hydrogen;
- Kite balloons, with a streamlined shaped and tethered with cables to the ground, without a propulsion system but with trimming mechanisms to derive stability from the air winds. Kites were destined primarily to military reconnaissance uses during the first and the Second World War;
- Airships, characterized as a lifting craft—the main sustaining device for lift—containing lighter-than-air gas (helium or hydrogen) that provides the adequate shape to the craft, with controls for steering and maneuvering the craft in flight. Airships are aerodynamically shaped, with a flexible, semi-rigid or rigid structure, and are equipped with a propulsion system and an underbelly for accommodating crew and passengers. In contrast to balloons, that can only follow the wind direction and can change altitude, airships have flight controls for maneuvering.

The balloons filled with hot air or gas (**Fig. 1**), receive an upward lift equal to the weight of the fluid which is equal to the volume of the balloon (Archimede's principle). The balloon can move upwards in the air when the lift received is greater than the weight of the balloon itself. The main difference between a hot-air balloon and one filled with gas is the means used to change altitude: the former utilizes burners to warm or cool the air in their shape, the latter uses to release ballast to climb and the venting of gas through

Figure 1 Hot air balloon at Holloman US Air Force Base. Source: <https://www.holloman.af.mil/>. Credits: Airman 1st Class Michael Means

appropriate valves for the descent. Modern free balloons are today used mainly for sightseeing tours, able to carry between 3 and 5 passengers, up to 10–12 passengers for larger sizes. Free balloons can fly at extremely high altitudes, up to 20,000 m.

Typically, hot-air or gas balloons for manned flight are made by a single-layered, fabric bag (lifting envelope), having an aperture at the bottom to release air or gas, with an attached basket or gondola for carrying passengers. Transport applications for balloons are for entertaining purposes, tourist rides on cultural and historical heritage sites, aerial photography, and sport events worldwide. Hot-air ballooning is recognized by the Fédération Aéronautique Internationale (FAI) as the safest flying sport in aviation, with rare fatalities occurred in flight, according to the NTSB.

The Rozier balloon (Fig. 2) is a hybrid balloon, deriving the name by the French scientist Pilatre de Rozier, combining helium and hot air in its envelope. For the take-off, the gas chamber is partially filled with helium, and as the craft is lifted, the diminishing

Figure 2 Rozier balloon Breitling "Orbiter 3." Source: https://en.wikipedia.org/wiki/Rozier_balloon#/media/File:Breitling_Orbiter_3_aloft.jpg. License: <https://creativecommons.org/licenses/by-sa/3.0/deed.en>.

Figure 3 Zeppelin Airship D-LZZF Baden-Württemberg shortly after the takeoff in Friedrichshafen, district Bodenseekreis, Baden-Württemberg, Germany. *Source:* [https://commons.wikimedia.org/wiki/Category:D-LZZF_\(aircraft\)#/media/File:Zeppelin_NT-DSC_9550.jpg](https://commons.wikimedia.org/wiki/Category:D-LZZF_(aircraft)#/media/File:Zeppelin_NT-DSC_9550.jpg). *License:* <https://creativecommons.org/licenses/by-sa/3.0/deed.en>. *Credits:* Dietrich Krieger.

atmospheric pressure makes the helium to expand. To stabilize at a certain altitude or descend, the helium is spilled through valves on top of the balloon. The Rozier balloons are technological sophisticated aerostats, employed in oceanic flights or circumnavigation of the Earth, and their operations are managed by a team of scientists, engineers, meteorologists, and technicians.

Airships are flyable thanks to a specific “torpedo”-shaped profile, made as a rubberized, fabric bag, inflated with lighter-than-air gas (hydrogen or helium), equipped with a propulsion system and flight controls for maneuvering. Historically, the first airship was built with a vapor engine in 1852, followed by an electrical propulsion airship and in 1898 by the first one with an internal combustion engine. In the same year Count Ferdinand von Zeppelin built its first Zeppelin LZ-1 airship in Southern Germany. The larger Zeppelin LZ-129 Hindenburg had a 245 m length, a crew of 40 flight officers plus 10–12 stewards, carrying max 72 passengers at a cruising speed of 125 km/h.

The use of hydrogen as an inflated gas was common since the beginning of the airship era, but due to its easy flammability it was abandoned after the Hindenburg airship disaster in 1937 followed by many other airship crashes. Helium gas, for its non-flammable properties, resulted the most practical lifting gas for manned airship operations and passengers transport.

A large utilization as a transport mean, at the beginning of the 20th century and at the onset of the second World War, made the airship the speediest air vehicle of the time over long transatlantic routes, able to be employed for commercial transport from Europe and the United States, offering passengers comfort and a luxury on-board service (Croccon, 1923).

The modern Zeppelin NT (New Technology) (Fig. 3), in operation since 1997, is a semi-rigid airship, with a high-strength multilayer laminate envelope, with structures made in carbon-fiber and aluminum, helium-inflated, driven by three propeller Textron Lycoming piston engines, capable to accommodate 14 passengers and 2 pilots, with a maximum speed of 125 km/h. Usually the airship flies at half this speed for sightseeing and tourism purposes.

Heavier-Than-Air Aircraft (Aerodynes)

Aerodynes are the heavier-than-air flying machines most commonly and widely known, categorized on the basis of the different way Newton’s law of dynamics is applied to generate the lift for the flight. Depending on the lift force generated for the flight, aerodynes are classified in three main categories:

1. Aerodynes with aerodynamic lift devices: where the lift is generated by the relative motion of a body through the airflow. The body-lift devices, moving in the oncoming airstream, encounter a certain amount of air masses due to the body-fluid relative motion at a certain speed. Because the body lift devices are characterized by appropriate geometrical configurations, capable to exert momentum to the airflow, air masses are accelerated downwards generating a field of pressure forces and a resultant upward lift on the body (Losito, 1982; von Karman, 2004).

Air vehicles lift devices are mainly platforms or wing surfaces, having several configuration types:

- a. Fixed wing surfaces (aircraft)
- b. Rotary wings, engine-powered (helicopters, quadcopters)
- c. Inclined platforms (stag beetle kites)
- d. Flapping wing surfaces (ornithopters)
- e. Self-rotary wings due to translational motion, with or without engine (autogyros)

2. Aerodynes with lift jet devices: where the lifting devices are mechanical systems (lift jets) accelerating air and gas with no body-airflow relative motion. Lift jets can be characterized as:
 - a. Cold jets released by ventilated, engine-actuated, fans
 - b. Hot jets released by turbojet engines or rockets
 - c. Mixed jets, released by turbojets which, through a turbine, provide the motion to ventilated fans accelerating cold air from outside downwards

Missiles are rocket-propelled vehicles but will not be treated in this article, because of their specific propulsion dynamics and utilizations and are not conceived as transportation means.

3. Aerodynes with mixed lift devices: using independently or concurrently aerodynamic lift as well as lift jets. VTOL/STOL air vehicles belong to this group.

In the general classification a major distinction has to be made between fixed-wing surfaces aerodynes (aircraft), which provide small accelerations to a large airflow mass, and rotary-wing aerodynes (rotorcraft), where the momentum variation is given to a small airflow mass, so that these flight vehicles are characterized by larger vertical accelerations.

As we have done for aerostats, we will follow the classification of [Table 1](#) for describing aerodynes and the corresponding nomenclature, and we will focus mainly on two major groups, with fixed-wing surfaces and with mobile (rotary) wing surfaces.

Air Vehicles (Aircraft) With Aerodynamic Lift Devices

As [Table 1](#) shows, these kinds of air vehicles—usually called *aircraft* in aeronautical terms—are classified in two main clusters:

- With fixed-wing surfaces, with or without a propulsion system
- With mobile-wing surfaces (rotary wings) with a propulsion system

Aircraft With Fixed-Wing Surfaces, With a Propulsion System

These types of aircraft—which is the largest group—are defined as manned air vehicles having a standard architecture characterized by ([Losito, 1982; Roskam, 2015](#)):

Figure 4 Aircraft general description and parts. Source: https://it.wikipedia.org/wiki/File:Aircraft_Parts. Credits: Dtom.

- the fixed-wing surfaces that generate the aerodynamic forces to fly;
- the nose cockpit for the crew and the fuselage, a central, fuse-shaped body, made in aluminum alloys and/or composite materials for mobile surfaces, having the role to transport payloads (passengers or cargo), acting as the main structural joint between the wing surfaces and the tail surfaces group (empennage); and
- the horizontal and vertical empennages, made by a fixed surface and a movable surface, or by a full movable horizontal and vertical surfaces (taileron), a very common solution for modern commercial and/or military aircraft, which are responsible for stabilizing the aircraft and make it highly maneuverable in flight.

The aircraft architecture (Fig. 4) is completed by some other movable surfaces, part of the wing—flaps, spoilers, ailerons, trims—as well as landing carriages and wheels and a propulsion system, being it a propeller-driven engine (turboprop), or a jet engine (turbojet or turbofan).

A standard aircraft is mainly operated on solid, prepared or unprepared, strips for take-off and landing operations. The Air Vehicle nomenclature in Table 1 also counts for other two special aircraft types equipped with propulsion systems: seaplanes and amphibians.

A seaplane aircraft is conceived for utilization on liquid surfaces, and it is capable of taking off and landing on water. Amphibian aircraft are a sub-class of seaplanes that can be operated on solid airfields as well as liquid surfaces (Fig. 5). Seaplanes and amphibians are further divided into two categories, float seaplanes and flying boats, the former are equipped with a pair of floats supporting the craft on water, the latter are larger aircraft with a capable hull, as its main bodies, that can carry more payload (Figs. 6 and 7).

Utilization is usually limited to aerial surveying over liquid surfaces (lakes and rivers), transport toward areas with limited access and airfields or for firefighting purposes. The development of seaplanes ended soon after 1940s, because of their poor aerodynamic and structural efficiency compared to land aircraft, and also due to the V-shaped configuration of floats and hulls that contributes to the increase in the body's aerodynamic drag (Vagianos and Thurston, 1970). Futuristic design proposals with a completely new aerodynamic configuration suggest that large seaplanes could be used for long-range airline operations, accommodating between 200 and 2000 passengers from new offshore airports (Levis and Serghides, 2014).

Aircraft With Fixed-Wing Surfaces, Without a Propulsion System

The most common and well-known manned aircraft without a propulsion system are gliders, or sailplanes. A glider is designed without engine and it is incapable of taking-off autonomously from an airfield, so it is towed by another engined aircraft to take-off, released at a certain altitude and from there it can only hover, using airstream currents (thermals) for climbing and fly appreciably long distances, and descend in gliding flight. Gliders have usually a small weight, wings with a high aspect ratio (more than 20–30) and a very streamlined aerodynamic shape for minimizing drag in flight (Fig. 8). Designed with a cockpit accommodating one or two pilots, at the most, gliders are generally employed for recreational flights or tourism. Also, the US National Aeronautics and Space Administration (NASA) utilize sailplanes for research purposes for investigating the airflow behavior over lifting surfaces (Fig. 9).

Aircraft With Mobile-Wing Surfaces (Rotary Wings)

Helicopter (Rotorcraft)

A helicopter is a manned flying vehicle with a main rotor (or rotors) mechanism with mobile aerodynamic surfaces (blades), and a smaller antitorque tail rotor, whose rotary motion develops the necessary aerodynamic forces for the lift, translation of the aircraft in the air and hovering (fixed point). The power the rotor needs for developing the drive, balancing the helicopter weight, enables to achieve vertical take-off and landing, ensures adequate evolutionary flight, in forward, backward, lateral directions and in hovering, providing the necessary thrust to overcome the resistance forces. The rotor is actuated by a turbine power plant. The first modern helicopter was the German Focke 61 that successfully flew in 1937, achieving a 3427 m altitude, flying at 122 km/h. A confirmation of these outstanding performances was the flight, years later, of the American V.S.3000, designed by Igor Sikorsky, which was the first of an interesting and long series of helicopters, reaching full-scale production in 1942, up to now.

The helicopter configuration consists of an aluminum alloy and/or composite material fuselage, with the nose cockpit for the crew separated by the passenger cabin, in most cases and for larger vehicles, or a whole smaller cabin with the seats for the pilots, a single 2–6 blades rotor actuated by the turbine engine, placed along the axes of the center of gravity of the machine. The helicopter tail, joint with a boom to the cabin, is equipped with a small antitorque rotor with few smaller blades, which enables the directional control of the vehicle (Fig. 10). Some helicopters of larger size and weight for heavy transport and cargo can have a tandem counter-rotating rotor, one mounted behind the other (Fig. 11).

Helicopters of different size, small or larger, are not comparable with fixed-wing aircraft, in terms of speed, altitude and performances, but due to their ability to take-off and landing very quickly from very small airfields or congested city centers, or even from platforms on top of residential buildings, they are employed in a variety of civilian roles, such as search-and-rescue, air ambulance for emergency medical assistance, aerial surveying, tourism, passengers, and cargo transport (Figs. 12 and 13).

Autogyro

An autogyro is the simplest *gyrodine* with a single rotor and flapping hinges, but with conventional aircraft controls for roll, yaw and pitch. The first autogyro prototype was designed by the Spanish Juan Codornio de la Cierva in 1923, and achieved success and acceptance, followed by other innovations. An autogyro is capable to sustain itself in flight at very modest speed and can also land exactly on a vertical axis, using a very limited surface to take-off because the rotor with flapping hinges can develop high air masses at low speed. Driving the rotor before take-off was achieved by a coiled rope system activating the rotor at a speed to 50% of that required. With the C.19 Mk.4 model a direct drive from the engine to the rotor was fitted, so the rotor could be accelerated up to the necessary inflight speed, and then disengaging the rotor clutch before the take-off run (Fig. 14).

Air Vehicles Categories by Types and Roles

According to the classification criteria of **Table 1**, air vehicles (aircraft) with fixed-wing surfaces and a propulsion system are subsequently sub-divided into two major categories: Civil Aircraft and Military Aircraft. These two major groups depend on the specific utilization types and roles the aircraft has been designed and built for, according to technical and customer specifications. Only Civil Aircraft will be discussed herein.

Civil Aircraft

Table 2 shows the categories in which civil aircraft are grouped. In the table, gliders, seaplanes, and amphibious have been already described in the section of Aircraft with fixed-wing surfaces and with a propulsion system. In the following, the three categories of aircraft for tourism (General Aviation), executives-business and commercial transports will be briefly discussed.

Tourism (General Aviation) Aircraft

This category includes aircraft for private, tourism and recreational flight, flying school and training, aerobatics and ultralight aircraft. As per ICAO international standard classification, aircraft in this category are divided in:

- General aviation (GA) aircraft
- Aerial work (AW)
- Commercial air transport (CAT)

A tourism aircraft is generally twin-seats, side-by-side, or in tandem, aircraft with a nose propeller engine, usually with a high wing aerodynamic configuration and fixed landing gear (**Fig. 15**). Aircraft for aerial work usually are employed for aerial survey and photography, parachute dropping, crop spraying, and banner towing (**Fig. 16**).

Aerobatic Aircraft

Aerobatic aircraft are single or twin-seater aircraft, with low wings and outstanding maneuverability and strength characteristics because of the high accelerations achieved in maneuvering during aerobatic air as shows in Fig. 17.

Ultralight Aircraft

Single-seaters with weight of up to 300 kg or twin-seaters with weight of up to 650 kg. These aircraft are similar to a general aviation aircraft but with a very light material structure and limited weight and stall speeds, due to regulations limitations. (Figs. 18 and 19).

Figure 21 Learjet 35, N880Z/591, Potomac Corp. *Source: Credits: Brian G. Nichols.*

Executive-Business Aircraft

Business aviation aircraft have intermediate size between general aviation aircraft and larger commercial airliners. Aircraft in this category have configurations with two or three turbojet engines, a pressurized cabin to operate at high altitudes (up to 15,000 m) and relevant cruising speeds (over 800 km/h). Business aircraft can accommodate up to 10–12 passengers, having cabins with elegant and outstanding interiors for business or corporate executives transportation and relative baggage.

The Cessna 560XL (Fig. 20) is 9-pax business jet with a cruising speed of 802 km/h, able to cover 3907 km range, and a maximum altitude of 13715 m. Another high-performance jet is the Learjet 35A (Fig. 21), 8-pax accommodation and a cruising speed of 852 km/h, it can cover a range of 4067 km and a similar max altitude, 12495 m. The Falcon 7X (Fig. 22), a great success of the Dassault

Figure 24 PIAGGIO P-180 AVANTI, D-IZZY/1034 (AIRGO FLUG SERVICE GMBH). Source: Credits: Brian G. Nichols.

business jet family in operation, is able to carry 12–19 passengers, depending on the configuration, a cruising speed of 904 km/h, a max altitude of 15,545 m and a range of 11,020 km.

Some small firms also use general aviation piston-engine or turboprop airplanes for their business and for commuting executives and personnel, due to the affordable operating and maintenance costs. The Partenavia (now Vulcan Air) P-68 (Fig. 23) is a 1990 kg twin piston-engine aircraft, hosting a weather radar in the nose, capable to carry six passengers with a cruising speed of 311 km/h. One of the most innovative project of executive aircraft is the Piaggio Aerospace P180 Avanti (Fig. 24), sporting a company-registered “Three-Lifting-Surfaces” configuration.

Figure 26 City Airline Embraer ERJ 135 (SE-RAA) landing at Birmingham International Airport, Birmingham, England. Source: https://it.m.wikipedia.org/wiki/File:City_airline_embraer_erj135_se-raa_ar.jpg. Credits: Adrian Pingstone

Equipped with a powerful two pusher-turbo-propeller engines, this aircraft exhibit a max cruise speed of 732 km/h, accommodates max 6–9 passengers and can carry 5 passengers over a 3240 km route. Some business aircraft types are also used for technological experimentation with special electronic equipment installation (Fig. 25).

Commercial Air Transport Aircraft (Airliners)

Used by world airlines for revenue air transport on assigned regional and international networks, these aircraft are designed on major specific requirements as range, speed, take-off and landing distances, comfort, and payload capacity. As shown in Table 2, commercial airliners are divided in passenger air transport and cargo, the former usually sub-divided in five large subcategories according to the fleet segmentation and to the specific market segment of utilization:

- Small regionals (20–60 seats), with range in the window 1482–2780 km (Figs. 26 and 27)
- Large regionals (60–100 seats), with range in the window 2410–5560 km (Figs. 28 and 29)
- Small single-aisle (100–150 seats), with range in the window 4080–7410 km (Fig. 30)

Figure 27 Crossair Saab 2000; HB-IZR@ZRH. Source: [https://commons.wikimedia.org/wiki/File:38cb_-_Crossair_Saab_2000;_HB-IZR@ZRH;23.08.1998_\(6115679325\).jpg](https://commons.wikimedia.org/wiki/File:38cb_-_Crossair_Saab_2000;_HB-IZR@ZRH;23.08.1998_(6115679325).jpg). Figure 28 Flybe (Stobart Air) ATR 72-600 aircraft taxiing at Manchester Airport. Source: <https://www.flickr.com/photos/levien66/27321615950/>. Credits: Transport Pixels

- Large single-aisle (150–220 seats), with range in the window 3700–7780 km (Fig. 31)
- Wide body (220+ seats), with range in the window 6950–16780 km (Figs. 32–34)

Regional aircraft can be equipped with two turboprop or jet engines, whilst the small and large single-aisles, usually called narrow bodies, are equipped with a couple of powerful turbofan engines. Wide body airliners have two or four, high by-pass ratio, turbofan engines.

Cargo Air Transport Aircraft (Freighters and Outsize Cargo Freight Transporters)

Because more than one-third of world trade value is carried by air, air cargo has become even more critical for serving specific markets demanding speed and reliability for the transport of goods. Freighter versions of large aircraft have, over the years, been developed offering outstanding capacity in terms of volume, weight, cabin dimensions, controlled transport, direct routing, and reliability. These aircraft are designed with very large cross-section cabins, some with space available for passengers, and cargo compartments to host containers and/or pallets where to house heavy loads, cabins offered with side doors and cargo loading systems for small as well as large loads.

The Antonov An-124 (**Fig. 35**) is a typical outsize freight transporter, it can carry a flight crew of 6 and 88 persons in the aft of wing carry-through cabin, with max payload between 120 and 150 tons, over 3700–4800 km, while the An-225 *Mriya* (**Fig. 36**)—the world's largest aircraft—established a world record of flying 253,82 tons load to 2000 m. Commercial payload attains 188 tons load.

Derived from the standard passenger version the Boeing B747-200F Freighter (**Fig. 37**) can deliver 90.720 kg of containerized or palletized load in its main cargo deck over more than 8340 km range. A very special conversion of the B747 is the B747 LCF Dreamlifter (**Fig. 38**), used to transfer B787 Dreamliner aircraft major sub-assemblies from one manufacturing site to another, with a maximum revenue freight load of 113 tons and a 8149 km range.

The Airbus A300-600 Freighter (A300-600F) (**Fig. 39**) offers a pure freight capability up to 54 tons over 4900 km range. A special outsize cargo freight transport version is the Airbus A300-600ST Super Transporter *Beluga* (**Fig. 40**), a modified version of the A300-600F, used for carrying complete sections of Airbus aircraft from the major European partners' production sites around Europe to the final assembly lines in Toulouse, France and Hamburg. The *Beluga* has a MTOW of 155 tons and is capable of carrying max 40 tons payload over 2779 km, or 26 tons payload over 4632 km. To support the company aircraft production rate increases Airbus

Figure 41 Maiden flight of the Airbus “Beluga XL” on 2018, July 19th at around 10:31a.m. Source: [https://commons.wikimedia.org/wiki/File:%22Beluga_XL%22_A330-743L_\(cropped\).jpg](https://commons.wikimedia.org/wiki/File:%22Beluga_XL%22_A330-743L_(cropped).jpg). A300-600ST *Beluga* will be gradually replaced by the A330 *BelugaXL* (Fig. 41), which performed its maiden flight in July 2018, and is derived from the A330 wide-body airliner. The *BelugaXL*, expected to enter service in the second half of 2019, will incorporate a highly enlarged cargo bay structure with modified rear and tail section.

Summary and Conclusions

Air vehicles are technological objects so diverse in terms of aerodynamic configurations, categories, and roles that a definitive classification cannot be exhaustive of the matter. The paper aims at giving the fundamental, widely renowned, and worldwide-accepted classification of aircraft utilized in civil commercial transportation, for both passengers and cargo purposes. The most important, almost unique, element chosen in the classification process has been the physical dynamic sustaining phenomenon by which an air vehicle derives its motion through the airflow, being the static lift for lighter-than-air flying vehicles—as aerostats—and the dynamic lift for heavier-than-air aircraft, classified as aerodynes. This latter cluster of air vehicles has been given the largest emphasis due to the technological advancements embedded in the particular aerodynamic configuration, with aerodynamic lift devices—for fixed wing or rotary wing aircraft—with or without a propulsion system, or specific flying solutions, as for the gyroclines. Also, a categorization of aircraft by types and specific roles of utilization has been presented, with emphasis on transport airliners and freighters, due to the importance this type of transportation plays in several world markets. Specific attention could be given in the future to manned-unmanned air vehicles objects, a category which will play a relevant role in the imminent future for urban and autonomous transportation over short urban routes and mostly for the technological advancements to be adopted by aircraft designers.

Acknowledgments

The author conveys his sincere acknowledgments to Carlo De Nicola and Francesco Marulo, professors, respectively, of Aircraft Aerodynamics and Aerospace Structures & Aeroelasticity in the University of Naples “Federico II.” A special acknowledgment for the valuable inherited knowledge is conveyed to the memory of our Master, Valentino Losito (1941–2002), professor of Applied Aerodynamics from 1967–92 in the same University and of Aeronautics in the Italian Air Force Flight Academy. To these beautiful minds of my university years, I owe the rigor and the disciplined approach toward the intricacy and the riveting secrets of the Science of Flight. Specific aircraft images in this article are courtesy of Mr. Brian G. Nichols, photojournalist, who is gratefully acknowledged.

Introduction

When Wilbur and Orville Wright made their first successful flight in 1903, aircraft manufacturing was an homework practise developed in the small shops or garages of experimenters and adventurers. The First World War and the significant superiority given by aviation pushed in a significant way the evolution helped of airplanes and their manufacturing out of the workshop and into mass production. Second-generation aircraft helped post-war operators to make start commercial use of them, particularly as carriers of mail and express cargo. Airlines, however, remained unpressurized, poorly heated with spartan interiors and accommodation for passengers and unable to fly above the bad weather. Despite these drawbacks, passenger travel increased by 600% from 1936 to 1941, but was still a luxury that relatively few experienced. The huge advances in aeronautical technology and the concomitant use of air power during the Second World War boosted the explosive growth of aircraft manufacturing capacity after the war in the United States, the United Kingdom and the Soviet Union. The availability of turbojet-powered civilian aircraft in the late 1950s made air travel faster and more comfortable and began a faster growth in commercial air travel. In the 1970–80s Europe has enormously developed the capability of designing and manufacturing passenger transport aircraft by the Airbus consortium who has taken advantage of the huge technological effort spent for the Concorde development, then invested in the A300/A320 development as well as in the turboprop ATR 42/72 family, the most successful commuter in the world. At the same time the development of military airplanes as Tornado, Eurofighter and Mirage/Rafale has in parallel made progressing the military aircraft manufacturing capabilities that has then been strengthened by the development of the large military transport airplane A400M, the first military program managed by the Airbus consortium. By 1993 over 1.25 trillion passenger miles were flown worldwide annually and this figure nowadays has almost quadrupled thanks to the introduction of new generation airplanes powered by very efficient engines and manufactured with the most advanced manufacturing technologies and materials. Thanks to this development the costs, weight and pollution have been drastically reduced, and the simultaneous development of airport infrastructure has contributed to the fast growth of the air transportation during last decades.

The Start of Aircraft Manufacturing

Aircraft may not seem to have changed much in the past few decades, but within the last half-century advances in how they are manufactured have been as great as the evolution in aircraft production over the first 50 years of aviation. Even tough from outside the airplanes may look like always the same, the technology hidden inside continues to evolve as industry drives down costs and weight. The wood frame, wire bracing and fabric skin of the Wright 1903 Flyer was setting the standard of the airframe architecture and manufacturing in the first decades of powered flight. Weight was the main concern for the first airplanes design and manufacturing and wood was the only light material that was strong enough. It was available and affordable, easy to work, resilient and repairable. The Flyer's long wing spars were made from spruce, and the airfoil-shaped ribs from ash. Cotton fabric was applied

Figure 1 1903 Wright Flyer—National Air and Space Museum—Smithsonian Institution. *Source: Wikipedia.*

provide strength and sealed with canvas paint. But wood-and-fabric structures were not that strong, so the wire-braced, strut-supported biplane became the first “standard” configuration (**Fig. 1**).

Wood remained the principal material, but structures rapidly evolved through World War I. Cantilevered wings with thicker airfoils and stronger box spars replaced draggy bracing wires, notably with the Fokker Dr1 triplane in 1918. In 1912 Deperdussin racer introduced the monocoque fuselage, formed of thin plywood layers over a circular frame—light, strong and streamlined. After the war, the Loughhead (later Lockheed) brothers and Jack Northrop developed a method of forming fuselage half shells from laminated spruce in concrete molds and produced the Vega, Orion and other successful monoplanes. The monocoque fuselage was lighter and offered lower drag, but was more costly to manufacture and more complicate to repair. This led to semi-monocoque construction, used in German Albatros fighters, for which load-bearing plywood skin panels were glued to longitudinal longerons and internal bulkheads. As metal replaced wood after the war, the semi-monocoque concept was replaced by the stressed skin concept, but to this day—along with the cantilevered wing—it still remains the prevalent aircraft structural configuration.

Flown in December 1915, Hugo Junker’s J1 was revolutionary—an all-metal, cantilever-wing, stressed-skin monoplane. Wood was light, but subjected to be damaged and deteriorated along the years. The J1 was made of steel; a welded fuselage frame covered with thin sheet and wing skins internally reinforced by panels with spanwise corrugations. But steel is heavy, and development of the lightweight aluminum alloy led in 1919 to the Junkers F13, the first all-metal transport aircraft. In the meantime aircraft such as the Ford Trimotor and Junkers Ju52 also used corrugated skins for strength, but these increased drag (**Fig. 2**).

The Riveting for Aircraft Assembly

The first riveted aluminum structure—standard for aircraft manufacturing for decades—was Hall Aluminum Aircraft Co.’s XFH naval fighter prototype flown in 1929. Shortly after, Hall built perhaps the first flush-riveted aircraft, the PH-1 flying boat. Flush riveting and butt joints between skin panels, rather than the dome rivets and lap joints then used, reduced drag and were famously featured in the Hughes H-1 racer, the streamlined, all-metal, retractable-gear monoplane in which Howard Hughes in 1935 set a world landplane speed record of 352 mph (Fig. 3).

First Attempts for Alternative Materials in Aircraft Manufacturing

By the 1930s, riveted sheet-metal construction dominated aircraft manufacture, but lack of aluminum availability during wartime brought a revamping in wood—notably with the de Havilland Mosquito. Plywood facings, bonded to a balsawood core and formed using molds, produced monocoque structures. Experience led de Havilland to use metal-to-metal bonding in the Comet jet airliner. This and other U.K. post-war aircraft used Redux, a strong and durable adhesive invented in 1942. In the 1950s and 1960s, Fokker made extensive use of metal bonding in the F27 turboprop and F28 twinjet airliners, as well as Saab on 340 and 2000 aircraft fuselage skin with bonded stringers or other business aviation aircraft (Cessna family) that have embodied this technology for reinforced skin panels (fuselage and wing) manufacturing.

First Born of Jigs and Tools in Aircraft Manufacturing

Through the 1940s, aircraft were assembled by building skeletal frameworks and attaching the skins. Fairey Aviation developed the technique of building an aircraft as a series of subassemblies in jigs. Fairey’s method involved installing the skin in a jig that provided accurate, repeatable part location, then attaching the substructure as individual parts or as a subassembly produced in another fixture. This technique became an industry standard and later on this concept was revolutionized by the Piaggio P180 fuselage manufacturing. This airplane is characterized by an evolutive shape of the fuselage with tight tolerances to keep the airflow as much as possible with lower drag and the fuselage is manufactured from outside to the inside where the formed skins are maintained in place by vacuum tools and then frames and stiffeners are riveted on (Gavazzi, 2001) (Fig. 4).

Aircraft Manufacturing from Blocks

One of the biggest “hidden” advances in aircraft manufacturing was the development of numerical control (NC) machining. This enabled complex structures such as bulkheads and integrally stiffened wing skins to be manufactured from solid blocks of alloy, rather than assembled from sheet metal—improving quality, reducing weight and saving time and cost. NC machining was slow to get interest and being diffused along with manufacturers, until in the 1950s the U.S. Army purchased 120 machines and leased them to industry. Today five-axis high-speed precision machining is standard for metal structures, mainly for wing panels manufacturing where integrally stiffened skins are often used to reduce eliminate the rivets especially for laminar flow wing design application.

Figure 5 Design drivers for aircraft zones design (left) and Aluminum Alloy evolution over last 80 years (right).

The Use of Lightweight Materials in Aircraft Manufacturing

Titanium's low weight, high strength and heat resistance made it ideal for high-speed aircraft of the 1950s and 1960s and the first titanium aircraft was the Douglas X-3 Stiletto, flown in 1952 and designed to cruise at Mach 2, where skin friction required the heat resistance of titanium. Capable of Mach 3.2, Lockheed's A-12 and SR-71 were also mainly titanium, and the material was to be used for the canceled Boeing 2707 supersonic transport, designed to cruise at Mach 2.7—faster and hotter than the conventionally constructed Concorde.

At the end of 1970s aircraft manufacturers started to look at the use of Carbon Fibers for aircraft component manufacturing and military aircraft manufacturer as usual were the forerunner of this technology. U.S. moved to carbon-fiber composite for wing skins on Boeing AV-8B, F/A-18 and Northrop B-2 and the airframe of the Bell Boeing V-22 tiltrotor. Later also civil aircraft manufacturers started to look at the use of composite for airplane manufacturing, in a first step for secondary parts manufacturing and the for primary structures as well.

The Evolution of Aluminum Alloys for Aircraft Manufacturing Application

Aircraft designer and manufacturers looked at aluminium with great interest. Infact aluminum has the best weight/mechanical strength/thickness ratio. Steel has a density of 7.85 kg/dm^3 and a mechanical resistance (R_m) indicative of 750 N/mm^2 , while aluminum alloys (in the annealed state) have a density of 2.7 kg/dm^3 and an R_m of about 240 N/mm^2 (or less) respectively. As can be seen, the weight/strength ratios are similar and this means that a steel sheet with the same strength would be 1/3 thicker than that of an equivalent aluminum alloy sheet, but this will have implied problems and concerns about the mechanical stability of the fuselage and wing skin panels (Sollo, 2010)

In the continuous infinite race aimed at increasingly reducing the weight of airplanes, over the years aluminum alloys with increasingly high strength characteristics have been developed. Moreover different alloys have been specifically developed and tailored for the different applications on different areas of the airplane where the design drivers are different, depending by the dimensioning loads of the different aircraft components (Niu, 1995) (Fig. 5).

The Carbon Fiber Development for Aircraft Manufacturing

The first carbon-fiber primary structure in a production commercial aircraft was the vertical stabilizer of the Airbus A310-300, first flown in 1985. It marked the beginning of a progression of increasing composites use in the European manufacturer's airliners that added the horizontal stabilizer with the A320 in 1987 and A330/A340 in 1994 and the center wing-box and aft fuselage of the A380 in 2005.

However the first-generation carbon structures were labeled “black aluminum” as their designs were carried over from metallic airframes and did not make full use of carbon fiber’s benefits, as well as, being the composites a completely new and unexplored technology for the Certification Authorities, stringent conservative safety factors were applied and the airplane resulted in a significant overweight. The most significant example of this “black aluminium” approach was the Beechcraft Starship, a canard business aviation airplane that was designed during 1980s and was conceived as a full composite airplane. At the end the airplane was in a significant overweight and this caused the airplane to fail and only 53 airplanes were built (Fig. 6).

A different approach was undertaken in the same period by the Piaggio P180 AVANTI (three lifting surface airplane developed in the same period) where the use of carbon fiber laminate composites was limited to the tail, to the forward wing and to engine nacelles (Gavazzi, 2001) (Fig. 7).

Today the P180 airplane is still an innovative high performance airplane after more than 30 years from its design start and has been celebrated also for the Aviation centenary in 2003 at NBAA (National Business Aviation Association) Exhibition together with Wright brothers airplane (Fig. 8).

Figure 8 P180 Celebration of 100 Years of Flight (left) Avanti EVO Airplane (right). Source: Courtesy of Piaggio Aerospace.

The lightness, stiffness, and corrosion resistance of carbon-fiber composites led to their use for 50% or more of the structural weight of the Boeing 787 and Airbus A350. But carbon-fiber airframes imposed a return to costly manual layup and assembly (Fig. 9).

The aerospace industry is nowadays entered a period of unparalleled growth in the use of advanced composites (which currently comprise predominantly epoxy resins), with the advent of the Airbus A380, the Boeing 787 'Dreamliner' and the Airbus A350 XWB that has been the first Airbus constructed with both fuselage and wing structures from composite. It is difficult to predict where this

Figure 9 Material map for B787 manufacturing. *Source: Wikipedia.*

growth in composite usage in civil airliners will end, as at least half the weight of both 'Dreamliner' and A350 XWB comprises composites (50% and 53%, respectively), with large carbon fiber panels and fuselage frames made from this material (Denkenaa et al., 2016).

The composite industry's aim is therefore to develop processes whereby large sections, such as the entire fuselage or wing can be made from one piece of composite and also done so in an automated process. This process is now possible thanks to the advent of complex machinery able to impregnate carbon fiber and automatically lay it on a mold according to a predefined pattern that reproduces the design lay-up. One of the leader in this sector is Coriolis, that has developed the first robot Automated Fiber Placement (AFP) solution to comply with aerospace standards for both Thermoset, thermoplastic, and dry fiber manufacturing ability and that is capable of unique convex & concave geometry realization (Fig. 10).

This class of AFP machinery characteristics are the following: capable to manage single fiber from " to 1½", with cut and feed repeatability* ± 2.5 mm at 1 m/s and compaction force range 150–1000 N. The maximum lay-up speed is up to 1.2 m/s that provides very large efficiency combined with a tolerance between course laid up on separate tapes $+2.5/-0$ mm (Lan et al., 2015).

The result of this extensive use of carbon fiber composite structures is a move to more integrated structures to reduce parts count and more automation to drive down costs. The early-2000s Beechcraft Premier and Hawker 4000 had filament-wound fuselages, but automated fiber placement became the industry standard, coupled with new nondestructive inspection techniques. Moreover today the use of thermosetting material is widely diffused versus thermoplastic that have still limited applications in the aerospace field (Fig. 11).

Figure 10 AFP Equipment. *Source: Courtesy of Coriolis Composites.*

Figure 11 Extension of Composite Carbon Fiber application on most relevant civil and military airplanes of last 50 years.

Fiber Laminates

Between aluminum and carbon fiber is a family of materials, fiber metal laminates, that have found limited but important applications in aircraft manufacturing. Fatigue concerns with aluminum led in the late 1970s to development of an aramid-fiber-reinforced aluminum laminate, Arall, by TU Delft and Alcoa. However flat-sheet Arall had cost and manufacturing issues and this led to a second-generation glass-fiber-reinforced aluminum laminate, Glare, which is resistant to fatigue, impact damage, lightning strikes and fire burn-through. Suitable for double-curved panels, high-strength Glare is used in the Airbus A380 fuselage.

The Glare panels are conformed for alternate layers of aluminum alloys (approximately 0.3 mm thick) and a polymeric compound (plus or minus 0.2 mm). The polymeric compound is made from long fibers (50%–60% by weight) and epoxy resin as a matrix. It is called the configuration formula for the number of aluminum sheets/number of sheets of polymeric compound.

Figure 12 Crack stop mechanism in GLARE panels (left) and crack growth comparison (right) of bare Aluminum 2024 (green curve) vs Glare (blue and red curve).

Figure 13 Laser beam welding concept (left) and X-Ray photo of typical welded stiffener (right). *Source: courtesy Piaggio Aerospace.*

Figure 14 FSW concept (left) – Demonstrator aircraft fuselage panels with welded frames and stiffeners (right). *Source: courtesy Piaggio Aerospace.*

Very directional properties, imposed by the fibers. Its main advantage is the exceptional fatigue behavior in the longitudinal direction. The crack is triggered and propagated only for aluminum sheets. The fibers contain the load therefore the concentration factor of on-board loads is smaller, and also the speed of growth is less. Second, the crack grows, the speed decreases, even stopping (Fig. 12).

Rivetless Structures for Aircraft Manufacturing and Assembly

In an attempt to reduce as much as possible the manufacturing costs, huge effort have been allocated in the development of affordable and automated process aimed to eliminate rivets from the airframe by means of welding technique to join structural components without riveting. Just as reference the time needed for the installation of one rivet is about 1.5 min of two workers that multiplied by several hundred thousand of rivets distributed of the whole airframe of a modern commercial airplanes justify the effort of finding alternative solutions to riveting even if automated (SAE, 1994), to further speed-up the manufacturing and assembly of complex airplane structures. Two welding techniques have been developed in aerospace manufacturing: laser welding and friction stir welding. Laser beam welding (LBW) is a welding technique used to join pieces of metal through the use of a laser. The beam provides a concentrated heat source, allowing for narrow, deep welds combined with filler material use. The process is particularly suited for single curvature stiffened panels where no complex welding pattern had to be realized and the first industrial application of this technique has been done in 2000 on Airbus A318 lower fuselage panels where stringers have been welded to skin (Fig. 13).

The Friction Stir Welding (FSW) is a type of solid-state friction welding in which the melting temperature is not reached in the material to be welded and there is no supporting material. FSW is mainly used to join aluminum alloys (Akshansh et al., 2019) that would otherwise be difficult to weld with other techniques. It was invented in 1991 by The Welding Institute (TWI) of Cambridge (Fig. 14).

This technology has been for the first time implemented in the manufacturing of the airframe of the Eclipse 500, a Very Light Jet (VLJ) aircraft designed by Eclipse Aviation that has been the first certified aircraft with welded structure in 2006.

Aircraft Final Assembly Line

The current trend in aircraft assembly, is to have available equipped aircraft segments on the final assembly line (FAL) that are joined at different station of the FAL and more often these segments are manufactured by different partners and/or subcontractors.

Figure 15 Typical Final Assembly Line Sequence of a Business Aviation Aircraft. *Source: Courtesy Piaggio Aerospace.*

Generally the FAL is shortened to a limited number of station (4-5) and this approach allows to concentrate the integration of high value equipment at the end of the aircraft assembly, thus shifting closer to the aircraft delivery the most significant cash flow thus allowing a faster recovery of the invested cash (Fig. 15).

Future Trends

3D printing, also known as additive manufacturing, is making its way into the large-scale manufacturing process. Recently, Boeing teamed up with Oak Ridge National Laboratory to 3D print the largest single piece ever made using this technology—a 777x wing trim tool. The tool was printed in just 30 h, something that usually takes three months with traditional manufacturing methods. In addition, Airbus and Rolls Royce have revealed plans to begin 3D printing parts for the Trent XWB-97 engine used in the A350-1000. Continued integration of this technology could turn the shipment of aircraft parts into an electronic exchange of 3D printing blueprints. While this technology is still in the initial phases, adoption on a major scale has incredible implications for the industry, including vast efficiency increases, large-scale reductions in the amount of manufacturing waste and tremendous changes to aircraft manufacturing and the supply chain (Werkheiser, 2014).

Conclusions

Over the past few years, the aircraft manufacturing industry has seen countless innovations coming to fruition with many more on the horizon. The advancement made are enormous and more and more innovation are expected in the next decades to achieve the target set for the aircraft of the future: the zero-fuel aircraft. The recent surge in interest has put pressure on global aerospace and defense industries to create a long-term development strategy for the zero-fuel aircraft concept and drive market growth. This pressure is put not only on new propulsion system development, but also aircraft design and manufacturing to reduce weight and then reduce the power needed for the propulsion. The emerging technologies as 3D printing will be more and more developed and may be that in a short a full 3D printed aircraft airframe will not be a dream but will become reality.

Biography

Antonio Sollo is the Chief Technical Officer and Head of Design Organization of Piaggio Aerospace managing the whole Design Office activities for all airplanes of Piaggio Aerospace. Accountable Manager for DOA obligations according to EASA PART 21 requirements. He has a deep knowledge of the aeronautical product, having covered various roles in several aerospace companies from the civil and military transport sector (Alenia/Leonardo 1987–2001), Business Aviation and UAV (PIAGGIO AEROSPACE 2001–13 and 2018 up today), General Aviation (OMASUD 2015–17). Multi-year experience in Aircraft Structural design (both Metallic and Composite Structures), Flight Technologies disciplines, Certification disciplines, Interior & Exterior Noise disciplines, Innovative Manufacturing Technologies (Composite Structures, Metallic Build-up and Machined Structures, Welded Structures). As Manager of Piaggio Aerospace Structure Department as well as Piaggio Aerospace Technical Manager of Pozzuoli Design Office he has managed complex projects such as P180 Avanti II and III, P1XX aircraft development and has managed the whole aerostructure supply chain for the P1XX project and all the research on the next-generation composite primary structures (Fiber Placement, Infusion, RTM, Out of Autoclaves). He also defined the whole airframe preliminary architecture of the PIAGGIO AEROSPACE UAV family (P1HH and P2HH) as well as being the Chief Engineer of the MPA aircraft during pre-development and development start. During OMASUD experience, he has managed the whole company and defined the entire industrialization phase and launch of serial production of the SKYCAR Airplane (first two serial airplanes delivered to launch customer) and of a fully carbon fiber airplane REDBIRD. He also worked as consultant in various fields (rail, naval and automotive) and held teaching in Aeronautical Engineering Technology Manufacturing at the Aerospace Engineering Faculty of Federico II University of Naples. He is the author of many papers presented at national and international congresses, chairman of various sessions at congresses of the AIAA Aeroacoustic Association, Evaluator of research projects of V, VI and VII FQ of the European Community, EUREKA and IWT.

Introduction

The transport system is a fundamental element of cities. It provides opportunities for the development of cities' economic activities, allowing for their growth and well-being, and also gives their inhabitants access to jobs, education, health, and mutual interactions. A key challenge for cities is how to implement efficient transport systems, both from the operational and environmental viewpoints, to allow a harmonic and sustainable urban development.

Urban transport networks must offer mobility opportunities for a multiplicity of movements, both of passengers and freight, between spatial locations that can be far apart, and for a large diversity of trip purposes, hours of the day, and days of the week. The modes used vary with the socioeconomic level and the characteristics of the activity system of each city.

Using the Millennium Cities database, [Aguilera and Grébert \(2014\)](#) compared modal shares among different regions in the world. They found that 47% of trips used motorised private transport (cars and motorbikes), 37% corresponded to non-motorised transport (walking, bicycles), and only 16% used public transport. The cultural, socioeconomic and physical differences among the cities compared help to explain the significantly different modal shares observed ([Table 1](#)).

Note that the proportion of trips by car is especially high in North America. Public transport use reaches 45% in Eurasia, but only 19% in Latin America. Non-motorised transport accounts for nearly 50% of urban trips in Asia Pacific and Africa, 30% in Europe, and less than 10% in North America. Note also that in spite of the strong socioeconomic and cultural differences between Latin America and Europe, the aggregate modal shares in both regions are remarkably similar.

These aggregate figures show that, sadly, the main urban transport mode is still the private car, who has played a historic role in the economic development of countries and has become an integral part of the movement of people in all cultures. Its use is not only explained by its practical advantages (flexibility, comfort) but also by deeper psychological aspects such as status, social norm and affective variables that are behind habit formation; these aspects are a barrier for car users changing to other modes.

However, and considering its reduced carrying capacity, the automobile is a highly inefficient mode in terms of road space use and also produces strong negative externalities in the form of congestion, accidents and environmental pollution. It is just not possible to conceive a sustainable urban transport system based on the private car.

The rest of the paper is structured as follows. Section Urban Mobility Hierarchy presents a recommended hierarchy for urban mobility, under the principle that road space—scarce by definition—should be prioritised for its use by the more efficient and sustainable modes. Section The Role of Paratransit in Modern Transport Systems discusses the role of paratransit in modern transport systems and section The Shared taxi: A Chilean Paratransit mode considers, as an example, the case of the Chilean shared taxi, which could be seen as a modern paratransit mode. Finally, the last section summarises our conclusions.

Urban Mobility Hierarchy

Among urban planners and transport specialists there is consensus about the need to prioritise road space for the use of more efficient and less contaminating modes. Multiple alternatives may complement each other to generate feasible (i.e. efficient and

Table 1 Aggregate modal shares in different world regions

Region	Public transport (%)	Non-motorised transport (%)	Motorised private transport (%)
Eurasia	45	20	35
Middle East	10	35	55
Asia Pacific	18	50	32
Africa	5	50	45
Europe	15	30	55
Latin America	19	38	43
North America	3	8	89
Global	16	37	47

sustainable) transport options, and several countries have recognised the need to focus transport planning and road space assignment into these.

We classified the alternatives to motorised private transport in just two categories above (non-motorised transport and public transport), ignoring the ample variety of vehicles and services available to provide feasible movement alternatives, as well as the importance and potential role of each. Now, we consider a mode classification that emphasises the need to guarantee the mobility of people (and goods) rather than vehicles. This urban mobility hierarchy can be represented as an inverted pyramid where modes allowing for movements with more positive effects for the urban environment receive a higher priority (**Fig. 1**).

The top two tiers of the hierarchy contain alternatives that, together, are now known as *active modes* (i.e. movement is propelled by energy provided by the traveller). Walking does not only interact with practically all remaining modes (as most require access and egress walks), but also constitutes a relevant option for short distance trips. Thus, it is the fundamental link between land uses and the transport network.

The bicycle also presents important benefits in terms of cost, health and the environment. While it allows users to cover longer distances (in Santiago, Chile, it has been shown to be unbeatable for trips up to 7 km), it has problems in terms of comfort and convenience that renders its use lower than expected given its undeniable advantages. The provision of dedicated infrastructure (i.e. cycleways) and complementary facilities (like secure parking and showers) should help to increment its attractiveness.

The next tier in the hierarchy contains public transport. The formal transit systems' supply consists of regularly programmed vehicles with the capacity to move users with a variety of origins, destinations and trip purposes. Usually, the formal public transport modes are classified by vehicle type as follows:

- Buses: Reduced size vehicles (up to 150–200 passengers/vehicle) with routes that may be adapted in time following demand changes. Due to their cost efficiency, buses can serve areas with different population densities, offering shorter access/egress distances than other transit modes. Notwithstanding, the absence of dedicated infrastructure (i.e. bus lanes and bus only corridors) implies irregularities in travel and waiting times that affect their reliability. BRT implementations tend to resolve this problem through adequate interchange infrastructure and road separation.
- Metro (underground) and suburban trains, are high-capacity modes, operating at higher speeds through completely dedicated infrastructure, but with stations that are more separated than bus stops. These tend to be the preferred mode of public transport users, because of their comfort, lower travel times, higher regularity and network simplicity. However, their much higher investments costs only justify their presence in networks with very high demands.
- Light rail (LRT) and trams operate with mid capacity vehicles at relatively low speeds, generally on the surface, either sharing the way with other modes or through exclusive lanes. Although they have lower investment and operational costs than heavy rail, the level-of- service offered to passengers tends to be lower, especially in terms of travel time, regularity and reliability.

**Figure 1** Urban mobility hierarchy. Source: Adapted from Bradshaw (1992)

We will not discuss the next tier, freight transport, but it is obvious that a city cannot live without a well-designed freight and logistics system, so it is of utmost importance that planning considers the movement of freight in harmony with the rest of the system.

Finally, at the bottom of the hierarchy are cars and motorbikes, normally known as private transport. These are the least efficient and less sustainable urban transport modes. Although there is scant published information about the role of motorbikes in urban areas, in several countries of Asia and Latin America they have become a plague, leading to far more fatal accidents and almost equal congestion than cars. Cars, on the other hand, have been amply studied and it has been shown that their marginal external cost/passenger^a is about 10 times higher than that of buses in the peak period, and nearly 2.5 times higher in the off-peak (Rizzi and de la Maza, 2017).

Making people change from cars to more sustainable modes is difficult, among other things, because car users have strong attachments to their mode (status, habit) over and above its intrinsic qualities. To make car users consider other alternatives, it is first necessary to give priority to public transport and to charge car users for their externalities (i.e. congestion pricing). This has been done successfully in several cities and is certainly a way forward. Another good news is that younger people are more concerned about the environment and consider almost unhealthy to be a habitual car user; this has led to a strong increase in the share of active mobility, particularly in Europe, but also in other regions. Finally, there is scope to consider the potential benefits of modal integration. As mentioned, walking is an essential component of any public transport trip; therefore, we need to guarantee that access, egress and interchanges have an adequate quality and be comfortable to users. Likewise, several cities in Europe and North America have been successful in terms of integrating the bicycle with public transport modes, either by providing adequate cycle parking at bus stops or stations, or by allowing the bikes inside public transport vehicles.

Finally, public transport services must be planned such that their various modes satisfy specific roles better adjusted to their design. For example, heavy rail and LRT should cover high demand origin-destination pairs, complemented by BRT, while normal buses and less formal modes (i.e. *paratransit*) may be used to cover zones with lower density, providing greater capillarity to the network.

The Role of Paratransit in Modern Transport Systems

The public transport modes discussed earlier are formal, in the sense of being regulated by the respective authority. However, in many regions of the world the difficulty of providing formal public transport services at times and locations where not enough demand exists, prompts the spontaneous emergence of complementary or alternative informal services. Such *paratransit* services help to fill the wide space between private transport, on the one hand, and conventional, regulated public transport on the other.

While a consensus definition of *paratransit* does not exist, we will take as reference the one provided by Gwilliam (2002) “... any publicly available passenger transport service that is outside the traditional public transport regulatory system.” This definition^b is ample enough to include a myriad of transport options, including motorised vehicles (from taxi-like services provided by motorbikes, cars and minivans) to non-motorised vehicles (bicycles, bici-taxis, rikshaws, etc.), but excludes vehicles reserved for private use and those forming part of the conventional transit system.

Paratransit services become more relevant for the population when conventional transit systems are less developed. They are perceived as versatile and flexible, providing mobility alternatives in areas with difficult access or low coverage by traditional services. In certain cases, *paratransit* services may become an important alternative and even outclass the established transit system. In such cases, the transport authorities may be forced to recognise them as part of the established system, turning them legal without losing their informal flexible/adaptive essence.

This flexibility is one of the main advantages associated with *paratransit* services. These are *gap-filler* services complementing the major transit network in terms of coverage, frequency and adaptability to market changes. By operating with small vehicles, they are able to provide lower waiting times and a greater feeling of comfort and security. On the other hand, as the services are essentially private initiatives, they tend to be the only public transport mode in cities with low availability of economic resources to finance formal public transport systems.

However, the operation of *paratransit* also brings significant societal costs. For example, the use of small vehicles increases congestion, as larger fleets are required to satisfy demand. Likewise, it is not uncommon to observe operative malpractices favoured by the lack of regulation, such as service over-supply in peak periods and insufficient frequencies in the off-peak, lack of coverage in routes with smaller demand, discretionary fares and “street competition” for passengers by different services. Finally, they also generate negative economic effects derived from their market informality, such as inappropriate vehicle maintenance and social security problems for their staff.

In summary, it is not clear whether *paratransit* has effectively a global social benefit. For this reason, the behaviour of authorities has tended to evolve from ignoring (or even fighting against) them to making them formal and regulate their operation. The next step should be helping them to modernise and become an integral part of the formal system, recognising their supporting role to urban sustainability, both as a complementary mode to the formal system and as an alternative to the indiscriminate use of the car.

^aThat is, considering congestion, pollution, and accidents.

^bThis definition is valid for developing countries. In first world countries, *paratransit* tends to concentrate in providing regular services for special demands, such as old age pensioners, people with reduced mobility, and so on. These services are not considered in this chapter.

The Shared Taxi: A Chilean Paratransit Mode

To illustrate the role of *paratransit* options in middle income countries, we present a case study about the *shared taxi*, a typically Chilean mode that—although regulated and constrained in certain aspects—shares some characteristics with *paratransit* services operating in other parts of the world.

Mode Characteristics

The *shared taxi* is minor transit mode that operates in Chilean cities using cars with a maximum capacity of four seats, a predefined coverage area and a route which is, in principle fixed (but that can be adapted to the passengers' needs, especially at its ends). Historically, this flexibility has allowed its operation as a complementary mode to the major transit network (mainly composed by buses), in zones and periods with low coverage or level-of-service below par. The services started spontaneously as private initiatives that the Ministry of Transport has mildly attempted to regulate for quite some time^c. The degrees of freedom set by current legislation make it close to the *paratransit* standard. However, there is not absolute freedom to choose routes and both vehicles and drivers must satisfy certain norms.

Shared taxi operators have low levels of professionalism (services are usually managed by the vehicle owners or by third parties that hire them). The lines are not proper firms; rather, they represent associations of owners/operators belonging to a certain coverage area, who administer basic facilities but do not coordinate departures, level-of-service or fare collection, as all these depend directly of the driver. This precarious operation level, without economies of scale, is a main obstacle for regulation by the authorities.

Some Basic Indicators

Although the participation of *shared taxi* in the transport market of Santiago, Chile's capital and main conurbation is relatively low (Table 2), it increases at night and in the periphery of the city. In the rest of the country, however, the panorama changes; in fact, in most mid-size cities (between 200 and 500 thousand inhabitants) the mode's market share has been under constant increase, in some cases (Arica, Iquique-Alto Hospicio) overtaking the share of the formal transit system.

This increasing demand poses an important challenge in terms of regulation by the Chilean authorities, especially because it has affected the buses and has had perceptible congestion effects in the urban centres of the affected cities.

What Motivates Shared Taxi Users? An Experiment in Santiago

A revealed preference (RP) survey was designed and applied to a sample of current users of bus, metro, *shared taxi*, and combinations. Apart from data about their current trip and socioeconomic characteristics, we gathered information about relevant attributes (travel cost and times, in-vehicle, walking and waiting) for both the chosen alternative and for the others in each individual's choice set. Using a 5-point Likert scale, we also collected a set of perceptual indicators determined on the basis of focus groups with regular and occasional *shared taxi* users, with the aim of understanding their motivations to choose the mode.

Table 2 Shared taxi modal shares in Chilean cities over 200,000 inhabitants

City type	City	Population	Shared taxi proportion of total trips (%)	Shared taxi proportion of public transport trips (%)	Survey year
Conurbation	Great Santiago	6,254,000	4	13	2012
	Great Concepción	971,000	4	12	1999
	Great Valparaíso	944,000	7	20	2014
Middle size city	Coquimbo-La Serena	415,000	14	46	2010
	Antofagasta	354,000	10	26	2010
	Temuco-Padre Las Casas	309,000	8	22	2013
	Iquique-Alto Hospicio	295,000	16	55	2010
	Rancagua-Machalí	294,000	10	35	2006
	Puerto Montt	290,000	15	47	2004
	Arica	221,000	13	55	2010
	Talca	220,000	10	30	2003
	Chillán	216,000	8	31	2003
	Los Ángeles	202,000	13	45	2004

^c Regulatory measures, such as routes' norms and firm requirements, definition of maximum fleet size and prohibition to circulate through certain avenues, were set in the 90s and are still applicable through special laws that prolonged their validity.

Table 3 Perceptual indicators and CFA results

Perceptual indicators	Mean valuation	Confirmatory factorial analysis		
		Convenience	Reliability	Safety
1. Lower travel times	4.20			
2. Travel time reliability	3.60		0.350 (4.0)	
3. Possibility of travelling seated	4.32	0.325 (6.6)		
4. Possibility of carrying cargo	3.54			
5. Less transfers	4.18	0.386 (8.0)		
6. Lower waiting times	3.65	0.180 (3.0)	0.326 (4.0)	
7. Waiting time reliability	3.20		0.866 (5.2)	
8. Leaves me in a convenient place	4.38	0.539 (10.9)		
9. Less accidents	3.29			0.446 (4.3)
10. Less delinquency	3.60			0.863 (4.3)
11. Can make comments/suggestions	3.90			
12. The driver helps the passengers	3.61			

Perceptual Indicators

The analysis of these indicators revealed interesting aspects about the motivations of users for choosing *shared taxi* in Santiago (Table 3). The highest evaluations were associated with the comfort and flexibility offered by the service—Leaves me in a convenient place (4.38), Possibility of travelling seated (4.32), Lower travel times (4.20) and Less transfers (4.18). The worst evaluated aspects were: Waiting time reliability (3.20) and Travel time reliability (3.60), and the perception of safety in case of accidents (3.29).

The last three columns of the table show the results of a confirmatory factorial analysis (CFA) to test the existence of correlations among some of the factors and group them into potential latent variables. We found three such constructs: *Convenience*, *Reliability* and *Safety* which were used, together with the measured alternative attributes and individuals' socioeconomic characteristics, to estimate a hybrid choice model (Ben-Akiva et al., 2012; Bahamonde-Birke et al., 2015).

Hybrid Mode Choice Model

The RP survey allowed us to build a set of available routes, by metro, bus and *shared taxi* for each individual in the sample; these were used to model choices using a hybrid nested logit model incorporating the above-mentioned latent variables (Domarchi et al., 2019). A single *Bus* nest allowed us to treat the potential correlation between alternative bus routes for each individual.

The model's utility function incorporated several level-of-service variables—the ratio of the fare and the individual's wage rate (Gaudry et al., 1989), walking, waiting and in-vehicle travel time, and number of transfers. Some had interactions with the individual's socioeconomic or trip characteristics (i.e. systematic taste variations, Ortúzar and Willumsen, 2011, p. 279) and some also interacted with the latent variables. In particular, *walking time* was found to interact with *gender*, *Convenience* and having made a transfer; *waiting time* interacted with *age*, *Reliability* and with being a student. The variables *fare/wage rate*, *in-vehicle time*, *number of transfers* and *safety* had no interactions.

The results reveal that the marginal utility of walking and waiting time is similar and higher than that of in-vehicle time. Old age pensioners value waiting time significantly higher than the rest, and men value walking time less negatively than women. Also, users that had answered the survey after having transferred, value walking time significantly higher than those who started their trips near the contact point (for whom one minute waiting is equivalent to four minutes inside the vehicle).

High-negative weights assigned to walking time and number of transfers, confirm that users prefer more direct and convenient alternatives. The *shared taxi* is an attractive alternative precisely for these characteristics, in spite of not always offering the best travel or waiting times (including that some *shared taxi* users pay a higher fare). In terms of the latent variables, users who value the mode's *Convenience* have a significantly higher valuation of walking time than other users; also, those that find *shared taxi* more reliable tend to value waiting time (an attribute strongly correlated with reliability) less negatively. Finally, passengers that have a positive evaluation of the mode's security are more likely to choose it.

Summarising *shared taxi*'s flexibility is the best perceived attribute and can, in many cases, compensate for other characteristics perceived negatively or better provided by other modes. In Santiago, users value positively the convenience of having to walk less and require less transfers. They also value the possibility to reduce the egress walk time (through the mode's adaptability in its routes' ends) and to travel with higher safety. This way, *shared taxi* is perceived both as a complementary mode to the formal transit network (when there are no alternative options) and as a feasible and competitive option when there are other alternatives, even potentially less expensive and/or quicker.

Summary and Conclusions

Transport systems are suffering vertiginous changes in the world. The increasing economic power of many developing countries has implied a sustained increase in car ownership that, in turn, has brought in strong increases in congestion and pollution. On the other

hand, the climate change menace and the need to reduce transport emissions, have encouraged governments to design policies to disincentive private car use and to create feasible alternatives to achieve greater urban sustainability.

In this sense, the urban mobility hierarchy offers a valid orientation for planning in terms of promoting more sustainable modes. Active modes, such as walking and bicycle, are key in helping to reduce the obesity pandemic that is affecting developing and developed countries alike. Public transport plays a fundamental role in using urban roads efficiently to move large trip volumes (often for relatively long distance). This is done better when alternative modes in the network exist and act in a coordinated and complementary fashion, fulfilling diverse roles depending on the type of trip and user.

For these reasons, *paratransit*-like modes may play a relevant role, not only complementing the formal transit networks in certain zones or in periods of low coverage, but also by becoming a genuine alternative, valued by its users on account of its flexibility, coverage and comfort. In this sense, the Chilean *shared taxi* is paradigmatic. Our analysis reveals that the attributes valued more highly by its users are precisely those that allow a better adaptation to their needs; in its current status, this is associated with a relatively informal and scantily regulated operation scheme that, unfortunately, could represent a harm for society as a whole.

So, regulating *shared taxi* and *paratransit* modes in general—is a challenge for developing countries. The advent of *ridesourcing* platforms, such as Cabify or Uber, has brought a strong resistance worldwide by the taxi unions (and also by *paratransit* operators), who perceive them as an unjust threat, in lieu of their weak organisation and technological precariousness. If the Chilean authorities, for example, wish to maintain *shared taxi* as an alternative available to users, there is a need for clearly determining the scope and role of each mode—a subject still under discussion. In principle, one would expect the promotion of its complementary role to the formal public transport system (rather than as unregulated competition), especially in areas badly covered by the network, when it makes sense to maintain flexibility in routes and fares.

The need to plan for sustainable transport systems requires decisively implemented policies, under a solid institutional framework, appropriate legal instruments and enough audit capacity. Any modernisation process requires considering both operators and users. Also, the establishment of trade-offs between the need to maintain the attributes inherent to each mode and the welfare of the society as a whole. In this sense, regulation could be the doorway to the modernisation and integration of all public transport modes (formal and informal), but it also must have—as final goal—delivering better levels-of-service to users. Only in this way the public transport system will represent a feasible alternative to the private car, and will serve to building sustainable urban transport networks.

Introduction and Overview

This chapter will examine a variety of aspects of roads and forms of transport they have sustained and might sustain in the future. It will explore what the history of road transport might tell us about its future as well as some of the cultural meanings that surround road transport. The term “road” has often been used interchangeably with “street” and “path.” This has been historically true and somewhat at present, this chapter will consider “road” to refer to infrastructure that is of sufficient size and construction quality to be able to accommodate large numbers of persons and/or vehicles, generally at a velocity higher than that of streets or paths. “Street” can be generally thought of as an improved passageways in towns and cities that may or may not accommodate large numbers of persons or vehicles. It may be an extension of a road connecting more than one city or region or it may be an urban road that is designed or designated to handle less traffic than those known as roads. “Path” generally refers to a narrower passage that may or not be improved by humans, probably would not accommodate the mass movement of people and may or may not accommodate vehicles. Many paths, some in use for millennia, have their origins in animal tracks and trails.

After examining the history and cultural meanings of roads and road transport the chapter moves to an exploration of the present situation of road transport. The expanse of transport infrastructure as well as the extent of travel are presented. Types of modes constituting the major forms of road transport, from feet to the emerging automated vehicle, are discussed. The chapter then examines the types of modes and technologies currently animating discussions about the direction in which road transport might go in the future. Special attention is paid to that mode and technology most animating these discussions, the connected and automated vehicle (CAV). Questions are raised whether certain rapidly developing technologies, including drones and 3D printing, might render much road transport redundant. Three scenarios are then presented, each representing very different speculations about our future mobility on and off the road.

The Future of Road Transport has an Interesting Past

Roads were a relative latecomer to human and freight mobility. The earliest ways that humans traveled were by water, since many early settlements were along shores, or as hunters and gatherers moving in pursuit of food, traversing open terrain and savannahs, or following paths created by animals. When animal paths were created by large herds, such as buffalo in North America, the resultant paths were wide enough for wagon travel, as discovered by early settlers. Roads generally did not emerge until more humans began to live in cities and fixed communities. Road development was pushed along by the rise of larger political entities; regional principalities, kingdoms and early empires, that had an interest in moving large numbers of persons from one part to another either for military or commerce purposes. An early form of the dynamic, which exists today began; roads connect towns and regions and facilitate their growth, and their growth contributes to increasing the use of roads.

Roads were important for military and commercial purposes. The Great Wall of China was as much of an elevated roadway wide enough for substantial troop movement as it was a wall to keep out the herds of sheep, which accompanied and sustained invaders from the north. The vast and elaborate Inca (sometimes Inka) Road system was designed wide enough in most parts to allow substantial troop movement, but also controlled against invaders through a series of complicated suspended rope bridges which could be raised when necessary. The extensive roads and bridges of Imperial Rome served the purpose of moving large numbers of troops at rapid paces, often built over difficult terrain. It is worth noting that parts of these, and other well-built roads of centuries long past, are still in use today. (Hindley, 1971; Hyslop, 1984; Lay, 1992; Derry and Williams, 1993; Schiller and Kenworthy, 2018)

The terms transportation and communication were used interchangeably in previous eras since the relay of important messages and documents, whether by scrolls or the *chasquis* (language knotted into ropes) of the Inca, were transmitted by messengers along these routes. The Inca messengers ran at their top speed between relay stations spaced about 1.4 km apart throughout the kingdom. Even after the discovery and spread of the wheeled vehicle and the use of animals for human mobility the majority of persons on roads and paths were on foot and not always easy or safe. The relatively short trips between nearby towns could be difficult and hazardous. Much more so for the longer trips undertaken on foot for commercial or religious purposes. Often long distance religious pilgrimages involved some buying and selling of goods as well. The logistics of road travel were complicated and shaped by climate, especially seasonal factors, terrain, the existence of water and nourishment—for both humans and the animals accompanying them. Political considerations such as areas of hostility or taxation (tribute paying) led to the development of alternate routes skirting these areas.

What do Roads and Conveyances Mean to People? The Road as Metaphor and Symbol

A road is not just a road and a vehicle is not just a vehicle. Each has symbolic and metaphorical meanings that reach deeply into the human psyche and shape perception and experience for individuals and society. In order to understand the road transport of the future it is necessary to examine these meanings. Railroads as a major form of transport and its infrastructure are not addressed in this chapter as they are beyond its scope.

The road has often been portrayed, intentionally or not, as a way to a better and freer future. This has been true in painting, where the road is often the part of a composition denoting a journey or the future. In literature the road and its conveyances might have multiple layers of meaning. Mechanical vehicles, including bicycles, automobiles and trucks have often been seen as the means to achieve a desired future. A good deal of the treatment of vehicles and mobility in popular media reflects popular notions of why and how humans should move; quickly, comfortably, and with priority over other modes. Forms of mobility also shape how individuals relate to others and society; whether or how they interact with others and whether they accept regulations and fees as part of a motorist's responsibility—or whether they reject such as infringements on their "freedom to drive."

The Road and Travel in Literature and Popular Culture

From Walt Whitman extolling the pleasures of the wanderer on foot in his poem "Song of the Open Road" to Kerouac's automobile-based odyssey *On the Road*, to Neal Cassaday (the Dean Moriarty of Kerouac's novel) driving Ken Kesey and his Merry Pranksters across the country in the bus named "Further," as well as *The Motorcycle Diaries* by Che Guevara, the road and its modes of travel have been portrayed as a means to self-discovery and personal freedom.

The road and its forms of transport, including walking, have often symbolized life choices and changes. Robert Frost's popular poem "The Road Not Taken" (1915) as well as the Beatles' crossing of Abbey Road upon the completion of their last album together (1969), signify that change lies ahead. Roads have been important historically, and at present, for long distance travel by persons dedicated to a religious practice or to solitary searching. Pilgrimages, whether for religious or secular motives, involve many millions of persons on foot around the world each year, solo, or as part of groups, for short or long distances. These may be carried out under physically or climatically grueling conditions. Individuals who have logged thousands of miles on foot include the 1960s activist Peace Pilgrim (Pilgrim, 1991) and the folksinger Art Garfunkel's walks across America as well as other parts of the world (Schiller and Kenworthy, 2018; Garfunkel, undated).

John Steinbeck's *The Grapes of Wrath* (1939) chronicles the plight of a family displaced by the Oklahoma dust storms of the 1930s struggling to get to a better future. Their old car, overloaded with kin and furniture, sputters along, breaking down frequently, while their entry into the "promised land" of California is beset by formidable setbacks, symbolizing the societal break-down and obstacles to getting out of the Great Depression. The cover photo of *The Road Ahead* by Bill Gates, Jr. (1995) places the author in the middle of a rural road that stretches far into the distance as a metaphor for the rosy future that awaits us as internet technologies advance. The imagery and symbolism of road transport figure prominently in popular music ranging from "Daisy Bell" ("Bicycle Built for Two") of 1892 and "In my Merry Oldsmobile" of 1905 to Woody Guthrie's 1940s and 1950s folksongs, to the more modern car-rock songs of Bruce Springsteen, the Beach Boys, to the paeans to trucking and truckers such as "Convoy," as well as many contemporary rap songs glorifying fast cars and racing.

Road travel by modes deemed to be "fast," such as automobiles are not always so fast when subjected to a more holistic analysis, as that done by Ivan Illich in *Energy and Equity* (1976) (Illich, 1976). Fast modes of travel, from cars to planes and trains, have also been seen as "destroyers of time and space" (Schivelbusch, 1986; Sachs, 1992). Whether destructive or not, modern modes,

beginning in the 19th century, have definitively shaped social and psychological notions of time and space. While the speed of travel has greatly increased during the past two hundred years, the average of amount of time most humans are willing to commit to travel has remained relatively constant at about one hour per day on an average while the distances and the range of travel have greatly expanded (Marchetti, 1994; Whitelegg, 2016). The language and terminology of road transport have also been adapted, literally or metaphorically, into ordinary usage. Karl Marx wrote of revolutions as “the locomotives of history,” and terms such as “arterial,” “interchange,” and “hard drive” demonstrate such borrowing.

The Roads Frequently Taken

In order to discuss road transport in the future it is necessary to understand it at present. Road transport and travel is a vital aspect of everyday life for most of the planet’s people. Even for persons who do not travel much, road transport is crucial for the delivery of goods and services to them. The expanse of transport infrastructure, travel, and vehicle ownership is huge. But there is great variation in the extent of infrastructure provision, vehicle ownership and type of vehicle from one continent to another and, within continents, from one country or city to another.

The extent of roads and road transport worldwide and the disproportionate share of the United States, which constitutes only a little over 4% of the world’s population, is highly instructive (Schiller and Kenworthy, 2018). Worldwide there are over 64 million km of roads, approximately two-thirds of which are paved. The United States accounts for a little over 10% of these—although that does not take into account the fact that there are many multilane roads in the United States. When these are calculated there are almost 14 million lane miles of roads. The world motor vehicle population is approximately 1.3 billion and growing rapidly; personal motor vehicles (PMVs) constitute about 90% of these. The U.S. accounts for approximately 20% of these. Worldwide, on average—with significant variation between wealthier and less wealthy countries, there are 160 PMVs per 1000 persons; in the United States, there are 810 PMVs per 1000 persons. This motorization of everyday travel, sometimes termed “hypermobility,” or “hyperautomobility” (Adams, 2005; Freund & Martin, 2009; Whitelegg, 2016) has implications that are far reaching and affect many domains of human existence. These include human health and safety; environmental factors such as energy consumption, air pollution and greenhouse gases (GHGs), and urban heat entrapment.

Road Transport Safety and Health

Worldwide over a million persons are killed and as many as fifty million are seriously injured each year as victims of road crashes. In the United States over 37,000 persons are killed and 2,746,000 are seriously injured each year as victims of road crashes. Pedestrians killed by motor vehicles account for 15% of these deaths and bicyclists killed by motor vehicles account for 2% of the total deaths. The rates of pedestrian and bicyclist deaths and injuries from vehicle crashes are increasing faster than other categories reported (Dora et al., 2011; ITF, 2017; Smart Growth America 2019b).

Air pollution from road transport contributes significantly to human mortality. According to the World Health Organization (WHO, 2019a) each year some 4.2 million persons die prematurely from the effects of air pollution. The major pollutants include particulate matter (PM), ozone (O₃), nitrogen dioxide (NO₂), and sulfur dioxide (SO₂), all closely associated with road transport emissions and effects such as particulation from tires, brakes, and road surfaces—especially asphalt. Those living close to heavy traffic, especially the young and the elderly, are among those most affected and suffer high rates of asthma.

Particulates from tire and brake wear as well as tailpipes, and fluid drippings from motor vehicles also pollute bodies of water through road runoff. Emissions, such as the nitrates of oxygen (NOX) can be absorbed by bodies of water and can lead to acidification of these waters. Motor vehicle emissions, especially when smog-forming, also contribute significantly to acid deposition, or acid rain, which is very harmful of vegetation; especially forested and agricultural areas.

The transport sector, worldwide, is 95% dependent on fossil fuels for energy and the sector and its demands are growing rapidly. Motor vehicle emissions from road transport are a significant contributor to climate change and GHGs accumulation in the atmosphere. Transport constitutes about one-quarter of worldwide GHGs, with road transport as the source of about three-fourths of these; urban transport accounts for about 40% of these and about 40% of end-use energy consumption (WHO, 2019b).

In addition to pollution from emissions, transportation infrastructure itself has impacts which affect climate change such as the albedo and urban heat island effects which refer to the degree to which solar radiation reaching the earth’s surface and its structures is absorbed (and stored as heat in pavements, building facades, and rooftops) or reflected back and not absorbed. (Kelbaugh, 2019)

Major Modes, Energy, and Space Consumption

The major modes of road transport worldwide at present are: walking; cycling (including a growing number of electric bicycles or e-bikes), motorcycles, PMVs which includes standard automobiles, light pick-up trucks and sports utility vehicles (SUVs); transit vehicles; commercial and freight vehicles ranging in size from delivery vans to 18-wheeled tractor-trailer combination trucks. External energy consumption per kilometer by mode ranges from none for walking and cycling; to the relatively small amount of energy consumed by e-bikes and electric scooters, to a fair amount consumed by even the most energy efficient standard

Figure 1 Massive freeway interchange near Toronto, but could be almost anywhere in a North American metropolitan area. Note the separation of uses, lack of pedestrian and cycling connections between quadrants and the great distances between uses. *Source: Preston L. Schiller.*

automobiles, to large amounts for small trucks and SUVs, to very large amounts for large trucks (Vanek et al., 2014). When per capita energy consumption by mode is examined the personal vehicle modes are far less efficient than even transit modes at less than capacity. When energy consumption per unit of weight-distance is examined it is found that freight rail modes are greatly more efficient than road freight modes. The least energy efficient freight mode is air transport. (Schiller and Kenworthy, 2018)

The over-commitment to automobility and the support for the ever-expanding infrastructure devoted to sustaining it, also has significant impacts on the ways in which urban and suburban space is allocated and developed. Motor vehicles take up a fixed amount of area when parked—as they are for 90%–95% of the time, and an even greater amount while in motion. A technique for assessing the extent to which a specific road transport mode consumes urban space has been developed; the time-area concept, which demonstrates the great advantage that transit, walking and cycling have for preserving urban space, strengthening commercial districts, and fostering compact development (Bruun 2014) (Fig. 1).

“The future, like everything else, is no longer quite what it used to be.”

(Paul Valery, 1937)

Hands, feet, and attention-free driving; high velocity and safe spacing remotely controlled from a distant central authority; highways and interchanges engineered for maximum speed, separation of overlapping, or interconnecting roads from each other, and quick and easy connections with other roads; the relegation of pedestrians to separated way: Vanished are traffic frustrations and worries over getting to a destination on time—is this a current depiction of the near future of road transport we are entering? No, this is the world envisioned for 1960 in General Motors Futurama, Highways and Horizons exhibition viewed by thirty million persons at the 1939 World’s Fair at New York City’s Flushing Meadows (General Motors Corporation, 1940). Thanks to General Motors’ Motorama (1956) and its heavy influence over the creation of the national interstate highway system, begun in 1956, there were now plenty of suburbs for sleeping, modernist office towers for working in, and a huge network of separated multilane expressways crisscrossing the country side and traversing cities of all sizes along the way. Futurama II did nod at freight and passenger rail improvements giving them a little space in the median of expressways (Mayersohn 2014), especially those exploiting the resources of natural areas such as the Amazon (nywf64.com). But was this the bright future that had been expected? And will a number of modes undergoing development and refinement at present live up to their rosy expectations?

High-tech Proposals, Planning Proposals and Possible Scenarios

The future of road transport depends upon the outcome of the contest over which modes might prevail, the types of infrastructure that might be available to support these modes, the types of land uses that will dominate towns and cities, as well as the types of freight movement that emerge in reaction to these factors. The patterns of industrial and consumer demands that emerge in the future will also play a key role. All of these together may shape a future that is quite different from that which seems likely at present. The modes that are dominant or emerging now need to be examined in order to ascertain the likelihood that they will shape the future of road transport.

Issues around these factors include: How likely is the technology to emerge as promised or currently described? Who will likely use this technology and to what purposes? What is the likelihood of the technology’s deployment? What might some of the new

technology's unintended consequences be? How much public resistance will be generated in reaction to these changes? At present there exists considerable tension between promoters of new types of vehicles, often ones that greatly increase speed and reduce human control, and social movements, such as "complete streets," and "active transportation" which aim to reduce motor vehicle dependence through increasing the shareability and safety of urban streets ([Smart Growth America 2019a](#)).

CAV Stampede or Creep?

The mode that is dominating discussions about the future of road transport is the autonomous vehicle (AV) or the CAV. In its most complete form the AV would not be dependent on a human driver but to achieve this it would need to be telecommunications connected so as to recognize and interact with other AVs, the infrastructure it encounters or uses, as well as detecting or interacting with pedestrians, cyclists, scooters, and dogs and cats using the roads upon which it is traveling. For purposes of our discussion we will use the term CAV. Most depictions of CAVs indicate that they will be fully electrified which would simplify their engines and drive systems considerably, significantly reduce air pollution—at least locally, if not regionally, where power generation is not based on fossil fuels, and possibly reduce energy consumption on a per unit basis. Whether a transition to a 90% or 95% electrified CAV fleet would reduce overall energy consumption would depend on the extent to which it is used. Most analyses indicate that CAVs would lead to more driving overall ([Martin, 2019](#)).

The slow creep toward automating cars has been occurring since cruise control was first introduced in 1958 and came into wider use in the 1960s. Several semiautomated and semiconnected features have since been introduced including braking assistance, anti-swerve assistance, lane roaming alerts, parking assist, and computers under the hood—that can be hacked by mischievous experts ([Greenberg, 2015](#)).

The CAV, whether fully implemented as its promoters project, or whether only partially implemented through "AV creep" has significant implications for personal and freight mobility. There is wide-ranging discussion about whether the projected benefits of the CAV are mostly "hype" ([Schiller, 2016](#)) or of value if done carefully with new forms of transit applications ([Grush & Niles, 2018](#)) or likely but uncertain about its impacts ([Martin, 2019](#)). Some are already accepting the CAV as inevitable and suggesting ways in which such vehicles need to be designed to be least harmful and how our cities need to be redesigned to accommodate CAVs while protecting other street users and helping transit ([NACTO, 2019](#)). Unabashed promoters of the CAV for personal mobility include the automobile and high tech industries as well as several marketing interests. An internationally prominent marketing and opinion research firm has made grandiose claims for its future; promising that it will not only be more safe but that it will create more "me time," save money, reduce stress, and improve users' health. ([Ipsos MORI, 2016](#)). The promoters conveniently overlook the sobering implications of the origins of AV research; it was initiated and supported by the Defense Advanced Research Projects Administration (DARPA) beginning in 2004 as part of its interest in fostering the robotic battlefield of the future ([Schiller 2016](#)). Given the challenges facing CAVs, including whether or not they will or can be as fully implemented as their promoters claim, the reality may be one of creeping connectivity and autonomy.

Promising CAV Applications for Buses and Trucks

The use of automated controls for group transport vehicles in separated guide ways has been well-established in rail transit and people movers for several decades. There are some CAV applications that probably can be implemented in the near term which do not face as many of the issues raised by their wide-scale use for personal mobility. CAVs could probably be introduced into some road systems that are separated from general traffic and would not have to share their road space with other vehicles, including CAVs used for personal mobility. Some separated and access-controlled routes could be automated as is being done with the automated shuttle between the Gare d'Austerlitz and Gare de Lyon train stations in Paris. A number of other experimental AV bus uses have been introduced into relatively easy to control environments such as college and corporate campuses. One issue that has come to the fore is the very slow velocity, about the same as brisk walking, of the vehicles, which is a manifestation of the relatively underdeveloped state of the art of the sensor systems. In other locations, such as a separated busway, a full-sized bus could be both electric powered and automated. This is already happening in some cities in China and could be implemented in a number of North American busways.

The automation and electrification of the large truck fleet could have major implications for energy consumption, truck transport logistics and costs, and air quality ([Chottani et al., 2018](#)). Some of these, such as fuel and pollution reductions, could be beneficial, especially through electrification ([Martin 2019](#)). The automation of transit and freight vehicles would have serious implications for job displacement, since there are millions of persons employed as drivers, warehouse and others servicing the transit and trucking industries. While large trucks and buses are a relatively small portion of the total motor vehicle fleet, well under 10%, they consume fuel at a disproportionately high rate, as much as 20% of transportation fuel and are a major contributor to air pollution, especially particulate pollution, since almost all large trucks and most buses are diesel-fueled.

Large trucks that operate on controlled access highways could be a target for connected automation and electrification. Autonomous trucks (ATs) are currently in experimental trials, with human monitors on board in several locales, including 650 miles of I-10 between Texas and Southern California. Although the state of battery technology is advanced enough to project the possibility that all PMVs could be electrically powered in the future, it will likely remain insufficient for powering large trucks for many years. In controlled rights of way, and perhaps certain urban freight corridors, it might be possible to power such vehicles in the same way that most streetcars and light rail transit vehicles are powered; through an overhead wire or catenary system or possibly,

though less likely, a third rail—as some trains use in urban and airport transit. Hybrid and hydrogen fuel cell technology might be able to act as a bridge between present fossil energy sources for large trucks and their future use of battery power.

Trucking fleet automation could have significant impacts on freight logistics; it may accelerate the pace of “Just In Time” (JIT) delivery as well as displace a great deal of freight from rails onto rubber-tired vehicles due to its probable lower costs—perhaps as much as 40% lower (Tryggestad et al., 2017). This is a future projected from current realities and foreseeable technological improvements. But what might transpire if the need for commodity transport by road were to diminish considerably?

Could 3D Printing and Drones Replace Most Trucking?

If the technology of 3D printing were to continue to develop rapidly could most products, from small widgets to large buildings, be produced onsite? What might happen if most packaging, a major source of the bulk of transported commodities, were eliminated as a consequence of 3D printing? What might happen if the combination of 3D printing and drones replaced transfer warehouses, delivery vans and medium-sized trucks for local and regional deliveries? Would cargo containers, on land or sea, no longer be needed? What might happen to freight transport by road if a strong “3-Rs” ethic took hold such that citizens truly reduced consumption dramatically, reused to a much greater extent than at present, and only recycled when necessary? What might happen if 3D printing were developed to be able to use raw materials close at hand rather than relying on long-distance or even regional-local bulk commodity truck transport? (Sauerwein and Doubrovski 2018)

No More Need for Roads as We Know Them: Is Diminution of Motor Vehicle Travel Possible?

Road and street development in the United States in the post-World War II era, stressed maximum accommodation of PMVs and minimal or no accommodations for bicyclists and pedestrians. More recently concerns over the environmental and personal and population health effects of over-dependence on motor vehicles for personal mobility have been increasing. This has prompted the development of modifications or new forms of road transport infrastructure, also termed “complete streets,” (Smart Growth America, 2019a) as well as the greater use of smaller forms of mobility for some travel, such as various types of bicycles, cargo bicycles, and scooters.

When streets and roads are designed as “complete streets” with safe pedestrian and cycling features, the travel share of these “micromobility” modes often grows sizeably (Shaheen et al., 2019). When traffic calming, road diets, and pedestrianization are introduced commercial and retail zones often thrive more than before and downsizing the urban freight delivery fleet becomes a possibility. Various types of smaller right-sized delivery vehicles appear, from very small vans towing small trailers to various types of cargo bikes. Many are electric powered and some delivery services are shared by businesses so that only one service delivers to as many as several hundred enterprises in the same area, as is the situation for Gothenburg, Sweden (Eriksen, 2015). There are ways of addressing mobility, local, and long distance, including the conversion of existing excess road space to public transport, that would reduce environmental and social impacts without imprisoning us within the CAV or other questionable or harmful modes (Bruun & Givoni, 2015) (Figs 2–4).

Conclusion: Roads and Road Transport Face an Uncertain Future on a Planet Facing a Most Uncertain Future

Each of the three scenarios described earlier; full on CAV, CAV creep, or diminution of road transport, is at least partially rooted in existing trends. Whether any one of these prevails, or a hybrid of these, or, as Monty Python would have it, might it be “time for something completely different,” will only be revealed in years and decades to come. Ultimately, the future of road transport will depend on the shape in which the perennial struggle between the faster-further-riskier (personally and environmentally) wishes of those yoked to PMVs and CAV romance and those of aspirants to a slower-nearer-safer active transportation urging is resolved. Faster-further-riskier aspirants would likely welcome a CAV dominated future. Slower-nearer-safer advocates would likely favor complete streets, lane reductions and pedestrianization scenarios that encourage walking, cycling, scootering, and transit as well as vastly improved intercity public transport options. In a time of pandemics and increasing climate disruption, travel and JIT logistics might lose some of their necessity or allure and localization could become much more attractive, desirable, and necessary.

Biography

Preston L. Schiller, PhD, is a faculty member in the Master's of Sustainable Transportation program at the University of Washington, Seattle. He has taught at several universities, including the planning program of Queen's University, Kingston, ON. His interests have ranged from public health to autonomous vehicles. He has been an advocate for transportation and transit policy and planning reforms at local, state and federal levels in the United States and Canada.

Glossary

Cost-benefit analysis: Cost/Benefit Analysis is a technique for deciding whether to make a change. As its name suggests, it compares the values of all benefits from the action under consideration and the costs associated with it.

Generalized transport cost: It is the sum of all costs involved in a trip. For a business trip, this can involve the value per hour and the labor cost to the firm, as well as costs associated with the trip itself such as tickets, tolls, and vehicle maintenance.

Urban sprawl: Decentralization and suburbanization, also known as sprawl, has been associated with lower residential densities that cannot be efficiently serviced by mass transit systems outside specific corridors. Under such circumstances, transit is limited to a part of the city and citywide services become prohibitive.

Hub-and-spoke networks: These are networks serving a range of geographically dispersed locations through a central hub. This is generally more efficient, rather than operate direct services between locations.

Resilience: For a transportation system, resilience is the capability to recover from a disruption to an operational level similar to prior to the disruption in a timely manner. The longer and deeper the impact of the disruption on operations, the less resilient a transport system is.

Network effect: For transport networks, network effects are effects in other parts of the transport system as a result of a transport improvement.

Production functions: Production function estimates the maximum set of output(s) that can be produced with a given set of inputs. Use of a production function implies technical efficiency. Some of these functions include the transport capital stock as an input variable.

Trans-European transport networks (TEN-T): European Union (EU) program for the construction and upgrade of transport infrastructure across the EU, for all transport modes plus logistics and intelligent transport systems.

Accessibility Impacts

Accessibility can be defined as the ease of access to economic and social opportunities from a given location, by means of a transport system. The level of accessibility of a given place depends mainly on two factors: (1) its location, considering the spatial distribution of social-economic activities and (2) the quality of existing transport infrastructures. Places that have a central place in the economic system are more accessible than remote and peripheral areas. On the other hand, new and efficient road infrastructures, such as motorways, increase the accessibility of places by reducing travel times, transport costs, and increasing connectivity.

Improvements in road networks entail much more than a reduction of transport costs. They are associated with increased accessibility to labor markets, knowledge transfers between firms, and higher productivity levels. They are also related to regional development and the appearance of specialization and economies of scale. From a social perspective, road transport is essential to ensure access to basic services such as healthcare, education centers, or job opportunities. Consequently, increasing the accessibility of places is one of the main objectives of many transport projects/plans.

Accessibility can be measured with a wide variety of indicators (**Table 1**), which usually include two components:

- The cost of transport, expressed as distance, time or generalized transport costs.

Table 1 Most commonly used accessibility indicators.

Weighted average travel times	Shows the average travel time to a set of relevant destinations. Where A_i is the accessibility of node i , t_{ij} is the travel time by the minimum-time route in the network between node i and destination j (in minutes) and m_j is the mass (activity volume) of destination j .
$A_i = \frac{\sum_{j=1}^n t_{ij} m_j}{\sum_{j=1}^n m_j}$	
Economic potential	Shows the weight of accessible markets, discounted by the distance necessary to reach them. The closer to bigger markets the higher the economic potential of a given location. Where P_i is the economic potential of node i , m_j and t_{ij} are already known and α reflects the distance decay function usually calibrated with data from mobility surveys.
$P_i = \sum_{j=1}^n \frac{m_j}{t_{ij}^\alpha}$	
Cumulative opportunities	Counts the number of opportunities available to a certain location, considering a specific distance threshold. Where CO_i is the cumulative opportunities of node i , m_j is already known and δ_{ij} takes the form of 1 if t_{ij} is below a certain time threshold and 0 otherwise.
$CO_i = \sum_{j=1}^n m_j \delta_{ij}$	

- The attraction capacity of destination places that will depend on the study objective. Studies looking at accessibility to services may include the location of, for instance, schools, healthcare centers, and supermarkets. If the interest is to measure access to jobs or consumer markets, employment or population variables could be used.

A common practice for evaluating the accessibility impacts of road projects/plans is to compute the accessibility indicators for at least two scenarios: (1) a scenario showing the network after the road improvements and (2) a baseline scenario showing the road network before the investments. The comparison between both scenarios will uncover the areas where accessibility changes and impacts will be higher.

Fig. 1 shows the accessibility impacts of a hypothetical scenario of implementing tolls in the Spanish highway system. Notice that accessibility impacts are negative in this case, since the introduction of tolls will increase transport costs.

Land Use Changes

A change in road transport infrastructure may change the spatial distribution of land uses (Fig. 2). Increased accessibility levels brought about by improvements in road infrastructures may attract economic activities to the areas that benefit the most from these improvements. Some paradigmatic examples are shopping malls and logistic firms, usually located at highly accessible places such as road network intersections.

However, some studies point out potential negative effects associated with the construction of new roads, since some of the activities attracted to the area may be in fact relocations from less accessible regions.

As for the effects of road infrastructure in residential areas, some studies conclude that the decrease of transport costs and the promotion of private cars, linked to the extension of the road network in cities and suburbs, are related to urban sprawl. The land use changes caused by lower travel costs and greater accessibility can be controversial. On the one hand, roads are essential for economic and social activities to flourish, while on the other hand, they may lead to a relocation of economic activities and the dispersion of residential areas. In both cases, the construction of new roads may result in changes to activity patterns that can cause higher congestion levels due to the concentration of activities in certain places and to the increase of trip length because of urban sprawl.

Territorial Cohesion

Transport infrastructure and especially roads are essential to reducing regional inequalities and promoting territorial cohesion. Road networks are the most extended, connecting places that are not easily accessed by other modes. Increasing the accessibility of peripheral and rural areas to markets and essential services partly compensates for their remoteness and peripheral location.

The concept of territorial cohesion has been introduced in political agendas and in the impact assessments of transport policies, mainly since 2007 when it was included in the EU's Lisbon Treaty. The spatial distribution of accessibility is one of the variables used to measure the impact of transport plans on regional disparities and territorial cohesion. Dispersion and inequality distribution measures, such as the variation coefficient or the Gini coefficient, are some of the indicators used to analyze the level of territorial cohesion (López et al., 2008). When analyzing the impact of road network improvements on territorial cohesion, several studies compare the distribution of accessibility for the scenarios before and after a project. If the work has an impact on a limited area, and especially if improvements benefit places that are already very accessible, disparities between the most and the least accessible places will increase and the territorial cohesion impacts of such projects will be negative. If, however, road network improvements are spread out and benefit remote areas, the accessibility differences will be reduced and territorial cohesion will improve.

Figure 3 Territorial variation of spillover effects. Source: Own elaboration, based on [Laird et al. \(2005\)](#).

Road Network Vulnerability

The vulnerability of roads can be defined as the impacts associated with system failures (i.e., congestion, car accidents, earthquakes). The road structure contributes to different network vulnerability levels. Distributed, mesh-like networks are more resistant to random failures of nodes and links than centralized, hub-and-spoke networks. Furthermore, road links will be more or less vulnerable to traffic disruptions depending on their traffic flows and on the availability of good alternative routes ([Jenelius, 2009](#)). Studies show that consequences of road closures are higher in densely populated areas, where traffic flows are greater. At the same time, regions with denser road networks will be more resilient to any potential traffic disruption, as there will be more alternatives for traffic diversions. Accessibility indicators, such as those seen above, have been used to assess network vulnerability since they can explicitly consider the interplay between a system failure and the travel behavior of road users.

Vulnerability analyses are used to show the most vulnerable and critical links in a network. Critical links are identified as those causing the highest traffic delays/costs in the eventual case of a disruption. These analyses provide interesting insights into transport agencies regarding the improvement of network robustness and resilience to failure, through better network design and emergency plans.

Further Considerations on the Magnitude of Impacts and Spillover Effects of Road Infrastructure

The level of road infrastructure impacts depends on the quality and quantity of the existing infrastructure. Accessibility, land use, and territorial cohesion impacts will be particularly high in regions with less network density or where road network improvements lead to the elimination of existing bottlenecks. On the other hand, the effects of investments in regions with dense and efficient road network will be marginal. A similar situation occurs regarding the effects on the vulnerability of road networks since the impact caused by adding extra links to an already dense network will be residual.

Another consideration when measuring the territorial impacts of road infrastructure are spillover effects. Roads generate impacts that go beyond the regional borders where those roads are located. Improvements on the road network of a certain region may benefit distant regions, due to the network effect ([Laird et al., 2005](#)). Closely linked to the concept of network effect is the concept of spillover effect, understood as the benefits received by a region due to the infrastructure built in a different region. Spillover effects have traditionally been measured with production functions, based on the work of Aschauer ([Aschauer, 1989](#)), who found that the transport infrastructure plays a determinant role in GDP. More recently, some studies have applied accessibility measures to analyze spillover effects, arguing that transport capital stock figures fail to capture the usage of transport networks made by existing traffic flows ([Gutiérrez et al., 2010](#),). Accessibility measures have the advantage of considering the characteristics of road networks and their role in reducing distances and bringing economic agents closer. These studies show that spillover effects depend on the characteristics of the existing road infrastructure as displayed in [Fig. 3](#) and summarized further.

- A road located in the interior of a country/region will primarily benefit national/regional economic centers, and the impacts will be higher inside the country/region. However, accessibility benefits may spill over to neighboring countries/regions, as they use this infrastructure in their commercial relations.
- In the case of a new road located between two countries/regions, spillovers will be higher, given that more international/interregional connections will benefit.

- Spillover will be even higher in the case of road corridors crossing different countries/regions, since they will benefit a greater number of international/interregional relations.

Spillover effects have been measured to assess Transport Master Plans, the construction of new road corridors such as the Trans-European transport networks (TEN-T), or to evaluate the introduction of road charges. While spillovers are expected to be positive in the case of improved accessibility levels, they can also have a negative sign. If, for example, tolls are applied, transport cost will increase. Another example of negative spillovers lies in the increased congestion levels that may cross regional borders and cause delays in neighboring regions. Spillover effects have also been measured through the lens of territorial cohesion, as they will potentially change the distribution of opportunities across the space, benefiting regions that depart from a poorer situation (progressive spillovers) or, on the contrary, benefiting already well-served regions (regressive spillovers). Given the spatial nature of spillover effects, they can also be measured in terms of land use changes or network vulnerability, although studies in this respect are very limited.

Introduction

Encouraging walking as a safe, convenient, and practical mode of transport for everyday utilitarian trips is increasingly seen as an important step as cities around the world are grappling with how to move toward more sustainable transport systems based on low-carbon modes of transport. At the same time, efforts to make cities more livable and happy as well economically vibrant, and equitable places to live have become common policy goals at various levels of regional and city planning. Walking is perhaps uniquely situated to address a wide range of societal goals including reducing GHG emissions and traffic congestion; increasing social interaction, and improving air quality and population health.

Automobile-centric design, infrastructure, and policy of many urban areas worldwide have enormous environmental, economic, health, and safety impacts. The widespread use of automobiles is associated with greenhouse gas emissions and other pollutants with local, regional, and global impacts. In much of the world, privately owned cars are used for the majority of daily travel. In the United States, for example, it is estimated that over 80% of both work and shopping trips are by car. Transportation represents the largest single source of GHG emission in the United States (29%) (US EPA, 2015), of which the majority is from cars and light trucks. As well, the amount of space devoted to automobile movement and parking is associated with ecosystem disruption and issues related to storm water runoff and the urban heat island effect, and takes space that could be devoted to housing, green space, and other uses. Automobile-centric design of urban areas also has further impacts on human health and well-being including links to obesity and onset of chronic disease, traffic injuries and fatalities, and social exclusion. While some European and Asian cities have much lower car-ownership than what is typically observed in North America, the majority of daily trips are still taken by car in much of the world and most cities are actively attempting to curtail the dominance of the automobile for these environmental, economic, social, and aesthetic reasons.

Automobiles pose risks to people both inside and outside the vehicle. The World Health Organization estimates that of the roughly 1.4 million people killed in traffic crashes each year, 310,000 (23%) are pedestrians (National Highway Traffic Safety Administration, 2018). While technological and design advances have made cars safer for their occupants, pedestrian fatalities are also increasing more rapidly than automobile driver and passenger fatalities and now account for approximately 16% of all traffic-related deaths (National Highway Traffic Safety Administration, 2017). As speed and mass are the main determinants of injury severity in crashes between vehicles and people, the trend towards heavier vehicles and the fact the SUVs and light trucks represent an increasing percentage of automobile sales is troubling.

Background

Walking plays a foundational role in transport systems—all trips, regardless of primary mode, contain some amount of walking (whether it is traversing a parking lot, walking to a bus stop, transferring from one subway to another, walking after locking up or docking a bicycle). While not everybody is physically capable of walking on two legs, people of all abilities travel as pedestrians, sometimes using wheelchairs or other assistive devices. In addition, walking is available to almost all ages (except the very young and very old).

As the sole means of human mobility for millennia (until the domestication of pack animals, the development of boats, and the, much later, invention of motorized transport) walking plays a central and fundamental role in human history and the development of settlement patterns. Walking speed determined the size and location of settlements, villages, and cities. Until the late 1800s, the vast majority of major world cities could be traversed on foot in roughly 30 minutes. While “The Walkable City” (Speck, 2013) is often touted as a novel idea, it is important to remember that walkable urbanism was in fact simply the way cities were organized

until transport technologies such as streetcars, trains, subway systems and later cars stretched urban areas horizontally by opening up what could be accessed within reasonable travel times.

However, several decades of transport planning have prioritized the fast and efficient movement of cars over pedestrian safety and comfort. This prioritization has impacted the design of intersections, crosswalks, and pedestrian signal times meaning urban space is often designed in such a way as to discourage travel by foot. Pedestrian-focused safety improvements often face backlash from residents and other stakeholders if projects are perceived to slow down (car) traffic. Which is, in itself somewhat a historical if not ironic, as urban roads were not originally designed or intended to carry car traffic (as the surviving street grid of cities like New York and Boston, which have remained essentially unchanged since the 1800s can attest. The shift away from walkable urbanism, particularly in North America, has a myriad of social (Norton, 2011; Urry, 2004), legal (Shill, 2020) and political causes including post World War II mortgage reforms, the construction of Interstate Highway (Rose, 1979), and suburbanization of jobs (Brown et al., 2009). Other more recent trends include increasing amounts of “big box” retail located in suburban locations, which often are inconvenient, difficult, and dangerous to access on foot. While the evidence is not yet clear, online shopping is also likely to continue the trend away from residents walking to local shops for daily utilitarian needs. In addition, social norms, liability laws, and even how the media reports on traffic crashes (Ralph et al., 2019; Ralph and Girardeau, 2020) help reinforce the dominance of travel by car.

Bringing Pedestrian Issues Into Policy

Along with the increasingly ubiquitous term “walkability,” concepts or policy preoccupations such as the “8 to 80 City” (a city designed to accommodate anyone from the age of 8–80) and the “Fifteen Minute City” (all daily needs accessible within a 15 walk along safe and inviting paths), for example, have entered city-builders’ vocabulary when speaking about how cities can reallocate street space, prioritize active modes, and invest in intersection improvements in order to increase the attractiveness of walking. Subsequently, along with these new discourses in urban design, new policy approaches have entered city plans and budgets, (e.g., Complete Streets, Vision Zero, Safe Systems). In contrast to previous decades, pedestrian needs are now considered by a number of professions with a range of job titles, including planners, engineers, designers, and traffic monitoring specialists. Pedestrian issues are also addressed by other related disciplines such as economic development and public health, as the links to both the economic value and health benefits of pedestrian space is consistently highlighted by researchers (Sohn et al., 2012).

Simultaneously, pedestrian research has dramatically increased since the early 1990s, this goes along with the increased formal recognition of pedestrian issues in policy and legislative frameworks. More globally, the Vision Zero movement, started in Sweden in 1997 and based on the idea that traffic crashes are preventable and that the only socially acceptable number of traffic fatalities is zero, offers a system-focused look at road safety and moves beyond individual approaches to road safety. “Complete Streets” policies and initiatives have also blossomed in recent years, which attempt to bring in multi-modal approaches to street design and space allocation.

Measuring Walkable Pedestrian Space

Measuring and describing the elements of built form that encourage walking has been an important aspect of research on active travel for several decades. “Walkability” has become a common term used in both research and practice in a wide range of fields including urban planning, architecture, geography, public health, and increasingly in the media and real estate world. The term has been used in the academic literature since the 1970s (Abrams, 1972) and saw a resurgence in the 1990s and has since been used in a variety of settings to examine how neighborhood designs were associated with travel behavior (Owen et al., 2007), physical activity (Brennan Ramirez et al., 2006), and health outcomes, such as obesity and hypertension (Creatore et al., 2016; Hoehner et al., 2011; Ross et al., 2017; Rundle et al., 2016) as well as happiness, travel satisfaction, and emotional well-being (St-Louis et al., 2014). Influential work (Appleyard, 1980) also connected walkability to aspects of social interaction and social capital.

While some degree of confusion and lack of clarity around the term “walkability” exists (Forsyth, 2015; Shashank and Schuurman, 2019), most scholars and decision makers understand the term to refer to a quality of the built, natural, and social environment which allows people to access daily utilitarian needs (such as groceries, health care, transit stops, restaurants, cafes, retail stores, and green space) in an easy, safe, and convenient manner. It is therefore a quality of both the built form (street grid, quality of sidewalks) and the “content” (i.e., what is available to walk to, a function of land use mix and the location of various amenities) (Southworth, 2005). However, it is also, in many ways, a social construct, one that depends not only on the physical built environment, but on prevailing social attitudes and norms about what behaviors are expected or accepted in a particular location (be it on a scale of a country, city, neighborhood, or individual city block). Seniors and people with mobility issues or disabilities are forced to deal with crosswalk signalization that are often timed for people who move faster. In addition, some people (people of color and other marginalized people) face increased harassment by law enforcement while walking (Concepcion, 2014). In many locations, women encounter harassment and may feel uncomfortable and unsafe walking at certain times of the day. Therefore, the built environment is only one aspect of what characterizes a walkable space (Adkins et al., 2012). A truly walkable area would allow for anyone (regardless of race, gender, age, and ability) to safely and conveniently walk to desired destinations without fear of traffic danger, harassment by law enforcement or other street users, and along pleasant pedestrian paths.

Measurements of walkability rely on insights from Cervero and Kockelman's seminal 1997 work on the "3Ds" (Density, Diversity, and Design), referring to population and retail density, a diversity of land uses in close proximity, and a well-connected street grid design that makes walking trips feasible and comfortable (Cervero and Kockelman, 1997). Additional "D's" have been added to this conception (adding destination accessibility, and distance to transit to the original) (Ewing and Cervero, 2001), and later demand management and demographics (as a confounding variable in travel behavior) (Ewing and Cervero, 2010). Other scholars have also more explicitly incorporated safety and comfort (shade trees, street furniture, etc.), however, the 3D conception remains foundational in terms of how researchers conceive of walkable environments. Approaches of collecting data vary from audits (often using trained research assistants and systematic checklists, (Boarnet et al., 2011), surveys, remote sensing and GIS-based approaches to measure street grid and land use patterns (Manaugh and Kreider, 2013).

Researchers in the field have made distinctions around a hierarchy of walkable attributes in terms of their importance (Alfonzo, 2005). For example, Spoon (2005) identified four essential characteristics (mixed land use; accessibility/convenience; presence of pedestrian facilities; high connectivity), and a further five "encouraged" characteristics (street pattern; density; aesthetics; presence of parks, plazas and open space; traffic calming/street speeds). Similarly, Forsyth (2015) identified nine components of walkability of which four are considered necessary to achieve walkability (an environment that is traversable, compact or close, safe, and physically enticing).

Scholars have described a variety of additional factors at different scales (such as continuous, well-maintained sidewalks, crosswalk quality, separation of pedestrians from traffic, and landscape features (Lo, 2009). Another important area of research examines residents' perception of neighborhood walkability relative to objective measurements (Adkins et al., 2012; Leslie et al., 2005; van Lenthe and Kamphuis, 2011). Some focus on the needs and preferences of seniors (Negron-Poblete and Lord, 2014), or children (Buck et al., 2015).

Many of these measures and indices have been validated with travel behavior data and can help predict and explain the prevalence of walking (Adams et al., 2009; Frank et al., 2005; Owen et al., 2007), this is true even when controlling for residential self-selection and other confounding variables (Cao et al., 2009). However, there is compelling evidence that socio-economic status can modify the impact of the built and natural environment with, for example, members of poor, carless households walking even when conditions might not be seen to objectively support this behavior (Adkins et al., 2017; Manaugh and El-Geneidy, 2011; Riggs and Sethi, 2020; Steinmetz-Wood and Kestens, 2015).

Scholars have also suggested alternatives to the term "walkability" to encompass the wider health, social, environmental, and equity-related aspects of built, natural, and social environments that encourage active travel. Much of the confusion in the literature regarding measurement likely comes from different priorities and different behavioral outcomes of interest, for example, a street that promotes dog-walking or exercise might not be the same as one that allows for utilitarian shopping trips, "Walkable Suburbia" (Leinberger, 2010; Moudon et al., 2002; Southworth, 2007) looks different than a dense walkable downtown area. In recent years a variety of new approaches, such as walkalong interviews (Batista and Manaugh, 2017; Middleton, 2010), and Google street view analysis, sometimes using AI and machine learning techniques (Lu, 2019) have also deepened the conception of how to think about a walkable area.

Issues and Challenges

While walking can be a healthy, energizing, efficient mode of transport, the opportunity to access safe comfortable places to walk vary across socio-demographic factors. This has been explored by a number of researchers (Day, 2006; Ingram et al., 2017; Wolch et al., 2014). In addition to the enormous toll caused by automobile crashes, the risks of pedestrian injuries and fatalities are higher in low-income and racialized communities where residents often rely on walking as a daily mode of transport but where the local environment is not necessarily inviting and safe (Campos-Outcalt et al., 2003; Chandra et al., 2017; Morency et al., 2012; Rebentisch et al., 2019). In addition to evidence pointing toward large discrepancies in the provision of walkable urban space across income and racial lines, concern has been raised by scholars with regard to the possible gentrification and displacement impacts of improved pedestrian infrastructure (Bereitschaft, 2019). Large-scale pedestrian-oriented infrastructure projects (such as Manhattan's "High Line" and Philadelphia's Rail Park project) have been criticized for these impacts (Rigolon and Németh, 2018).

As well, in addition to discrepancies in provision of safe walkable environments, evidence points to differences in police enforcement (Concepcion, 2014) and driver yielding behavior (Goddard et al., 2015) making walking more dangerous and uncomfortable for people of color, and gender-based harassment that may, for example, limit the areas and times of day that women feel comfortable walking.

As perhaps a remnant of traffic engineering approaches, pedestrian planning and research has also struggled with how to approach design and analysis. For example, Pedestrian Level of Service (PLOS) measures rely on assumptions around the fact that maximizing pedestrian flow should be prioritized, as opposed to, for example, safety, comfort, and experience. In fact, planning for pedestrians raises important questions about the role and place of streets.

Many new transportation technologies have been introduced in recent years (and many lie just over the horizon). These technologies are often touted for their potential safety improvements as well as environmental benefits. Electric vehicles, for example, may reduce pedestrian exposure to vehicle emissions but may also introduce unintended negative consequences, such as being more difficult to hear, and maybe particularly so for blind pedestrians who are used to perceiving cars by sound.

Likewise, autonomous vehicles (AVs) present both opportunities and potential concerns for pedestrians. The emergence of highly automated driving systems has the potential to improve pedestrian safety, however, these vehicles may also have a variety of negative impacts from the transformation of urban form, travel behavior, roadway and vehicle design, and interactions between roadway users in unexpected ways. Many unanswered questions concerning liability and social and legal norms remain in terms of how these new technologies will impact pedestrian behavior and experiences. For example, will pedestrians be expected to change behavior, only walk in designated areas, or wear sensors in order to be detected by AVs?

The adoption of new forms of e-bikes, e-scooters, and expanding bikeshare systems have the potential to present challenges for pedestrians competing for limited amounts of street space. The needs of pedestrians and the social, environmental, health, and economic benefits of pedestrian travel should be fully considered in research and policy that incorporates these new technologies.

Planning for pedestrian space is also highly intersectional transport issue in that it is difficult to separate the many roles that the pedestrian realm plays (from a practical way to access desired destinations, but also a site of formal and informal meetings, a way to experience the social life of a city, as a place of protest, etc.) in a way that does not come to play to the same extent with other modes of transport. In this way, the many stakeholders who are engaged with the measurement, planning, and analysis of the pedestrian realm bring a variety of contrasting views, priorities, and ideas to the subject.

Opportunities for Change

Walking is a healthy, environmentally friendly mode of transport that is increasingly seen as an important part of a move towards sustainable urbanism. However, existing land use patterns, in addition to prevailing social and cultural norms are slowing the shift back towards walking being a common way to access daily travel needs. As Janette Sadik-Khan describes in “Street Fight: Handbook for an Urban Revolution,” (Sadik-Khan and Solomonov, 2016) cities can overcome resistance (be it from stakeholders in government and residents) to create healthy, livable and inclusive walking environments. New York City’s successful pilot projects closing streets to car traffic to allow safer pedestrian travel have pointed the way for other car-dependent areas to rethink the role of streets as solely for automobiles. Much of the history of transport planning in North America over the past century can be characterized by conflicts around the allocation of street space. These battles over the relative importance of different modes and mode users have been ongoing since the arrival of the commercially viable automobile in the 1920s and have dimensions related to environmental, social, and economic tradeoffs that have repercussions throughout society.

Writing this in the time of the 2020 COVID-19 lockdown of course opens the perspective on the importance of “walkability” as a way to ensure health, social inclusion, and safety for residents. Understanding where local residents can access food, health care, and green space while being able to practice physical distancing, is a vital public health and social justice issue. Somewhat optimistically, we can imagine that cities might learn from this experience how urban space has been devoted to cars instead of people. In early 2020, over 300 cities have significantly devoted space and budget to increasing the amount of pedestrian (and cyclist) infrastructure. What cities will learn medium and long-term remains to be seen. Tragically, the COVID-19 pandemic has also shone a light on the discrepancies in access to walkable space that scholars have been writing about for years, in terms of areas that lack quality sidewalks, green space, local amenities and how this is correlated to poverty and racialized communities. On a cautiously optimistic note, the speed at which municipalities were able to, at least temporarily, reallocate street space for pedestrians and cyclists in the time of a crisis illustrates that changes are possible and that a low-carbon transport system based on the comfort, safety, and convenience of pedestrians is possible and done in an equitable manner might be possible.

Introduction

Over the past decades, public transport has been introduced as a solution to solve many environmental and social goals in our cities. Bus transit service (or fixed-route bus transit systems) is the dominant form of public transport in most cities around the world and is the backbone of any public transport system. It comprises more than half of ridership compared to all other modes (e.g., commuter rail, light rail, paratransit, vanpool) in North America, where other modes are present.

While bus public transport system is a central element in the mobility in our cities, it is one of the most challenging systems to operate in an efficient and reliable manner due to the variety of internal and external factors that impacts its performance. External factors include weather conditions, traffic congestions and incidents, and demand variations, while internal factors include operators (or drivers) absences, scheduling and transferring problems, equipment failures, and other public transport modes (e.g., metro or streetcar systems) breakdowns. These factors present a persistent challenge for public transport agencies, hindering their ability to achieve the required level of service needed to enhance users' experience. Therefore, public transport agencies are in continuous search for new ways to enhance service quality, to retain existing riders, and to attract new ones.

Public transport users consider a system to be reliable only when they have easy access to the service (at both origin and destination) and with low and consistent waiting and travel times. To achieve these goals, over the past few decades, many strategies have been widely introduced to improve the bus service quality and users' experience.

This chapter starts with presenting an overview of several concepts and terminologies that was normally used in bus service operations. This is followed by a description of transit users' trip components and how they are weighing the importance of different components. This is, then, followed by a critical discussion of several bus transit service improvement strategies, while highlighting these strategies pros and cons. Finally, the chapter wraps up with a reiteration of the main conclusions.

Bus Transit Operations: Concepts and Terminologies

Good transport planning and efficient transit operations are required to balance the trade-offs among the goals, constraints, and values of transit agencies and passengers. *Transit service operations* refers to a wide range of activities done by a transit agency, which covers system management, scheduling, and functioning. *Reliability* is a key concept in the planning and operations of the public transport service. It refers to invariability of transit service attributes at certain locations. In the transportation setting, *service planning* involves the evaluation, assessment, and design and siting of transportation facilities. Other important operational concepts that will be used in this chapter includes *service headway and frequency*, *service capacity*, *bus stopping*, *running and travel times*, and *cycle time*.

The concepts of *headway* and *frequency* mean the same thing; however, they are often confused. *Headway* (h) usually refers to the time interval (in minutes) between two successive transit vehicles passing a fixed point (a stop) on a transit line in the same direction, while offering service for users. Headway is calculated based on departure times of successive transit vehicles. *Frequency* (f) refers to the number of transit vehicles that pass a point on a line (vehicles per hour). That said, it is the reverse of headway—a route with 20-min headway has a frequency of three vehicles/h. The mathematical relationship between both can be expressed as follows:

$$Frequency(f)_{veh/h} = 60/Headway(h)_{min} \quad (1)$$

There is always an important trade-off between users and transit agencies related to service frequency. Users are interested in shorter headway service (more frequent service) to minimize their waiting time. In contrast, transit agencies are interested in reducing their operational costs by operating fewer vehicles with large capacity (e.g., articulated buses, discussed later) rather than a large number of vehicles with smaller capacity.

Service line capacity (C) refers to the maximum number of users that can be transported past a fixed point in one direction during 1 h (or in a given time period). Therefore, the capacity of bus transit line is a function of its frequency and the used vehicle crush capacity (C_v). *Crash capacity* (or crash load) refers to the maximum number of passengers per bus targeted by the transit agency. Capacity is an important concept used by transit agencies to compare different vehicle types.

$$Capacity(C)_{passengers/h} = Vehicle\ capacity(C_v)_{Max.\ passengers\ per\ bus} * Frequency(f)_{veh/h} \dots \quad (2)$$

Running time (r_t) refers to the time that a bus takes to start travel from one station until it arrives at the next station in one direction along a route. It equals to the bus arrival time at the next stop minus bus departure time from the previous stop. *Stop time* (s_t) refers to the passage of time a bus spends at stops serving passenger movements. It equals to vehicle departure time minus vehicle arrival time at the same stop. The largest component of stop time is *dwell time* (or *passenger service time*). Dwell time is influenced by a considerable number of factors. These factors include passenger demand (more passengers getting on and off buses cause longer dwells), fare payment type (time required for fare validation), and vehicle and stop configurations (platform level, and vehicle number of doors and the number of channels per door). They also include vehicle passenger load (number of standing passengers on the bus, more standing passengers lead to longer dwells), door usage policy (alighting passengers exiting through the front door delay the start of the boarding process), and other issues related to bus lift (lifts are used to help seniors and people on wheelchairs to get on and off buses) and bike racks usage.

Travel time (T_r) is the time between departure from one terminal and arrival at the other terminal. It equals to the sum of running times and dwell times between departure from one terminal and arrival at the other terminal. *Terminal time* (t_t) is the time spent by a bus at a line terminal (Fig. 1). Terminal time (also called *Layover time*) is an important part of the bus operations practice. It is used to provide time to turnaround the vehicle, change driver, driver break for rest and/or meal, as a cushion to absorb and recover from delays. Terminal time is also used for while building bus schedules for schedule adjustment. *Cycle time*, C_t is the round trip time for a vehicle from the moment it leaves one terminal until the moment it leaves the same terminal after completing one cycle. *Deadhead time* refers to the travel time during which the bus is not in revenue service (e.g., travel from depot to start of line or travel between lines) (Fig. 2).

Bus Transit Users' Perception of Service Quality

A typical trip (door-to-door trip) for a passenger includes walking to transit stop (access time), waiting time at transit stop, on-board travel time in a vehicle, transferring time (to transfer between lines), on-board travel time in the vehicle, and, finally, walking to their final destinations (egress time). Passengers perceive the passage of time differently for each portion of their trip. Also, the above components can include driving to a park and ride rather than walking and not all trips include transfers.

Waiting time is usually perceived differently compared to the actual time (Psarros et al., 2011). During this time portion, users are exposed to irregular weather conditions as well as the adverse surrounding traffic, noise, and pollution. They also can be stressed by not knowing if the bus is arriving as indicated on schedules or not (Hess et al., 2004). Transferring between different routes has also an exponential effect on users' perceptions, leading to a considerable overestimation of their actual spent times (Iseki and Taylor, 2009). In contrast, typically, users perceived travel times an accurate manner compared to the actual travel time spent in the vehicle.

Figure 1 Bus running time, stop time, and travel time.

Figure 2 Bus cycle time and deadhead time.

Poor (or unreliable) service operations have undesirable consequences on both transit users and transit agencies (Evans, 2004). Transit agencies will have to provide an excessive buffer time (or layover time) between trips to absorb service delays and variation in travel times to make sure that the following trip starts on time. This means increasing the service cycle time, which will be translated into less frequent service, decreasing the quantity of the offered service to the public. Furthermore, travel time variability (or uncertainty) represents a problem for users, which they must account for during their trip planning process by employing *buffer time*. *Buffer time* is the additional travel time that users add to their trips to make sure they arrive to their destinations on time, demonstrating a direct impact of unreliable service on users' time.

In addition, variations in travel time between stops can further lead to bus bunching, particularly for frequent service of 15 min or less. *Bus bunching* (or *bus platooning*) occurs when two subsequent vehicles (or more) are not able to maintain the even-spaced schedule (in terms of time), and ending up traveling in close proximity to each other (as a platoon) and serving the same stops at the same time. Leading vehicles, in this case, get more delayed by picking up passengers, who are waiting for the next bus, and exacerbate the delays of the leading vehicle further and further. This is converted to a gap in the service that increases users' waiting time and vehicle overcrowding due to the uneven distributions of the vehicles.

For the previous reasons, passengers usually rate reliability as the second most important transit attribute after arriving safely at destinations. Transit users' behavioral surveys show that passengers consider service reliability twice as important as bus frequency (number of trips per hour). Furthermore, service frequency and shorter waiting time are more important than greater accessibility, because passengers prefer to walk more than to wait longer at stops.

Bus Transit Service Improvement Strategies

In the face of the previously discussed challenges and issues, transit agencies use several public transport preferential treatments and improvement strategies. *Improvement strategies* refer to any tactic used to improve the service operations and the perceived quality of the service. While, *preferential treatments* refer to a subcategory of measures that gives public transport vehicles advantage over other mode vehicles (i.e., private cars) at intersections or along the streets. Transit agencies employ a wide range of operational and physical improvement strategies that differ according to the required (or desired) level of improvement, capital and operational costs, and political acceptance.

The most commonly used strategies include transit signal priority (TSP), new buses (articulated buses and low-floor buses), reserved bus lanes, limited-stop services (express services), and service coordination and intelligent transportation system (ITS) (Diab et al., 2015). These strategies are typically combined to improve the conventional bus system's capacity, productivity, and reliability in addition to users' experience, and called *BRT/BRT-like* systems. BRT systems also come with special promotion campaigns and advertisings to separate them from local bus services. They are considered as one of the most economically effective tools to increase transit ridership that influences users' behavior.

Reserved Bus Lanes

Overview: Reserved bus lane (or dedicated bus lane) is one of the most effective strategies used by transit agencies along urban corridors. It refers to dedicating a traffic lane for bus service operations while prohibiting the general traffic from using this lane. There are different types of reserved bus lanes according to the infrastructure and traffic flow. Reserved bus lanes can be

semiexclusive, without any physical separation, allowing the general traffic to use the lanes at certain locations and segments (e.g., for turning movement at intersections).

Reserved bus lane can be operated only during peak periods or all day. They can be also fully exclusive, reserved of transit use at all the times, with a physical separation. Typically, these lanes are used for BRT systems, with some interference only at intersection from the perpendicular traffic. Therefore, they are combined with TSP systems at intersections (discussed later). Reserved lanes can be located adjacent to the curbside, offset to the lane adjacent to the curbside, or adjacent to the median.

Excepted impacts: Reserved bus lanes have considerable benefits for public transport service operations. They also have been associated with positive perceptions of quality of service by the users. More specifically, compared to bus operations in mixed-traffic lanes, reserved bus lanes improve transit service travel times, while decreasing service variations in most of the cases. This means a faster service observed by users as well as more predictable waiting and travel times. Transit users tend to overestimate their travel time savings associated with the implementation of such a measure.

For transit agencies, reserved bus lanes help in providing more accurate and efficient schedules due to the increases in service reliability. Nevertheless, these benefits can differ according to the level of delays experienced in mixed-traffic situation before the implementation of such a measure and according to the type of reserved lanes (semiexclusive vs. exclusive). In some cases, semiexclusive lanes slightly improve bus service travel times, with minimal or even negative impacts on bus service variations, due to turning movements at intersections and no-turn on red policy (i.e., right turns are not allowed on red) that used in some cities such as Montréal (Surprenant-Legault and El-Geneidy, 2011).

Ease of implementation: As reserved bus lanes have a physical impact on the built environment and transportation networks, the planning process for introducing reserved bus lanes needs to involve many stakeholders while assessing the potential impacts on other road users, adjacent properties, and the needs for law enforcement. Therefore, the first step in the planning process is to identify different stakeholders, which may include different department within the city (e.g., city's planning, public work, and law enforcement departments) and government agencies, in addition to local community members, private industries, businesses owners, and elected officials.

Due to the removal of traffic lane from car users, sometimes obtaining the appropriate political acceptance for the implementation of such measure can be challenging. Additionally, financial constraints in terms of providing the required capital cost for constructing such lanes can represent a barrier for their implementation.

Transit Signal Priority (TSP)

Overview: TSP is an operational strategy that gives priority to public transport vehicles at traffic-signalized intersections, facilitating their movement in a reliable manner. Transit vehicles typically experience substantial delays at traffic signals in busy urban areas. Therefore, one of the most popular strategies commonly used is TSP. TSP systems can be "passive" or "active." Passive systems rely on fixing the signal timing plans based on the expected transit vehicles' running and dwell times. They do not require any special technology for transit vehicle detection. However, passive TSPs provide minor benefits to no benefits, particularly if transit operations are unreliable and unpredictable. In contrast, active TSPs work on modifying signal timing in real time to provide priority treatment to a specific vehicle at a specific location (i.e., intersection) following its detection and succeeding priority request. Therefore, active TSP systems include hardware and software technologies: detection system, priority request generator and server, and communication system.

Typically, modifying the signal timing is done by activating "green extension" or "early green." Green extension strategy works upon the detection of a transit vehicle upstream of an intersection (within a specific window of time) while a green phase is active--this strategy extends the green phase. The extension maximum value of time (varies between 16 and 30 s according to the type of intersection, using Toronto as a case study). This value of time can determine the effectiveness of the strategy and minimize the number of failed extensions. Early green (or red truncation) works upon detection of a transit vehicle upstream of an intersection (within a specific window of time) while a red phase is active--this strategy shortens the red phase and returns of the next green phase. Generally, both approaches, green extension and early green, can be available together along a corridor; however, they cannot be applied at the same time.

Excepted impacts: TSP systems can significantly improve the transit vehicles' travel times by reducing their delay by an entire red interval (or around 90 s, using downtown Toronto as an example). However, in most of the cases, only fewer buses that arrive at the TSP equipped intersection within a short window of time benefit from this large saving. This means that these systems while typically having considerable impacts on service operating times may have a mixed impact on transit service variations.

Users experience travel and waiting times savings due to the implementation of TSPs. However, they tend not to overestimate these time savings. In other words, TSP systems have a limited impact on users' perceptions of changes in the quality of service in contrast to reserved bus lanes and other strategies that have a physical component that can be observed by users. Furthermore, potential negative impacts of TSPs consist primarily of delays to nonpriority traffic and road users and possible delays at neighboring intersections.

Ease of implementation: TSP is one of the most common and preferred strategies that have been used by transit agencies around the world. Since TSP is an operational strategy that has no physical impact on the built environment and road space, it is normally implemented with a higher degree of ease compared to other strategies (i.e., reserved bus lanes).

Regarding the cost of TSP implementation, in addition to a relatively high capital cost of system hardware and software components, considerable operating and maintenance costs are required to keep the system functioning in a reliable manner.

However, typically, monetary benefits of TSP systems' implementation, with regard to improved travel times and reduced delays, outweigh costs.

Limited-Stop Service (Express)

Overview: Limited-stop service is an effective strategy used by transit agencies along urban corridors. In contrast to local bus services, which serves all stops along the route, limited-stop service refers to offering that transport service only at major stops (in terms of ridership volumes) and transfer locations along a bus corridor. Limited-stop bus services could be offered in combination with local bus services. A good example is Montréal Route 467, which serves only 40% of the stops of its local route, Route 67 (Diab and El-Geneidy, 2013).

BRT routes are typically limited-stop routes. It should be noted that the concept of limited-stop service is often mixed with the concept of "express service." Express service is a limited-stop service in essence; however, it is used for long distance trips and for providing a direct connection between suburban areas and central locations (e.g., central business districts (CBDs)).

Expected impacts: Limited-stop services provide a faster service compared to serving only fewer stops and usually are associated with superior performance in terms of providing more predictable and reliable service. They have also an overall positive impact on users' experience and perceptions due to the addition of more buses that are fast and reliable.

For transit agencies, limited-stop services offer lower operating costs as vehicles can complete a cycle trip faster than the local services, leading to fewer buses and the possibility of adding more service (by increasing the frequency of service). The only trade-off, from the passengers' perspective, is related to the need to walk further to access destinations than otherwise needed with local services (Murray and Wu, 2003).

Ease of implementation: Limited-stop service is considerably simple and cheap to implement because it usually uses the existing infrastructure (e.g., bus stops and routes) compared to the previous two strategies. However, due to the previously discussed trade-offs, a delicate planning process that considers "local passengers" needs to access local destinations at stops and "through passengers" prospect of a faster service should be done.

From transit agencies' perspective, operating a local and an express service along the same streets can represent an operational and scheduling challenge. Transit agencies should make sure that local services are not delaying the express service or the other way.

Articulated Buses

Overview: Different types of vehicles can be used to deliver public transport services in urban areas. These vehicles include minibuses, regular buses (12-m length), and articulated buses (18-m length). Regular buses are the most commonly used bus type in North America. However, recently more transit agencies are incorporating articulated buses into the service. Articulated buses are mostly low-floor buses and normally used along the busy corridors with high ridership volumes. They provide between 30% and 60% more seats and standing capacity compared to regular buses.

Expected impacts: Articulated buses offer more capacity than regular buses, helping agencies in providing more capacity without changing the number of trips along corridors by replacing regular buses with articulated buses. Transit agencies also use articulated buses to reduce the number of buses (and operational costs) along corridors, while maintaining the same offered capacity. This reduction in frequency while may have a negative impact on user perceptions due to increases in waiting times, it helps agencies to maintain better service operations by reducing bus bunching.

Research has shown that articulated buses are slightly slower than regular buses; however, they are more predictable in terms of less service variations. Therefore, implementing these buses will improve transit agencies scheduling and reliability in comparison with regular buses. Along busy corridors, articulated buses have shown positive impacts on users' waiting time and travel time perceptions due to the increased offered capacity. This increased capacity raises the probability of finding a seat for users and decreases their anxiety for the need to wait for the following buses at transit stops, which occurs along busy corridors during peak periods.

Ease of implementation: Articulated buses are an operational strategy, which can be planned and implemented by transit agencies, with a minimum need for involving different stakeholders. However, if the agency is planning to reduce the frequency to introduce those buses, this will require consulting local passengers about the required changes. Reducing service frequency while maintaining the same capacity, for transit agencies, will decrease transit agencies' operating costs significantly (i.e., fewer buses equal fewer operators and less operational and maintenance costs). Nevertheless, for transit agencies, replacing regular buses with articulated buses while maintaining the existing frequency is associated with higher capital costs and potential higher operational costs that are associated with modifying maintenance facilities to accommodate the new vehicles and the need for more fuel (articulated buses are typically less fuel-efficient).

All-Door Boarding

Overview: Traditional fare collection method requires fare inspection and validation upon boarding a vehicle add a considerable amount of time to public transport service operations. Using data from Vancouver and Montréal in Canada, several studies showed that using exact change can take up to 4–5 s per passenger. In addition, while it takes around 3–4 and 2–3 s for using smart cards and for the visual inspection of flash passes, it takes only 1–2 s for entering the vehicle without presenting any fare. This shows a

considerable difference per passenger associated with the type of the presented fare versus no fare. Therefore, one of the most effective strategies to decrease dwell time at stops is to use all-door boarding.

All-door boarding (or prepaid fare, proof-of-payment) refers to moving fare collection off the vehicles and allowing passengers to use all the bus doors to board at stops. This strategy can be used only at a few locations along the system (major activity nodes and transfer location) or it can be used system wide.

Expected impacts: While there are many factors affecting bus dwell time such as the number of doors, number channels per door, alighting policy, nonlevel boarding, and bus crowding, all-door boarding strategies have proven to have considerable benefits on bus operations and user perceptions. All-door boarding reduces service activity time per passenger, resulting in dwell time saving that can reach up to 40%–50% compared to the base case of using exact cash. According to bus route location and structure, dwell times can encompass between 10% and 40% of the total trip travel time.

This previous dwell time and travel time savings are typically combined with significant decreases in dwell time and travel time variations, making the service more predictable, for transit agencies. From the users' perspective, all-door boarding has a positive impact on their perception of the quality of service, making their transfer seamless between vehicles at location with common all-door boarding areas.

Ease of implementation: All-door boarding strategies have an important physical component, which is related to the need of providing an extra space at stops for fare inspection and validation. This space is not always easy to acquire and requires changes in street design and sidewalk configuration. Therefore, a wide range of stakeholders should be involved in the planning and the implementation of such a strategy.

As a physical strategy, a considerable capital cost will be associated with the construction of the new stops and providing fare validation machines and areas. To cut capital costs, some transit agencies use "honor system," which allows transit users to get on and off the vehicles without presenting fares, while trusting that users have proof of payment. However, this system is still associated with a substantial loss in revenue due to fare fraud and the cost of hiring a large number of inspectors.

Service Coordination

Overview: Intramodal and intermodal transfers are routinely done by more than 40% of passengers in North America during their trips. Nevertheless, for low frequent services, transferring between lines can represent a serious problem for users due to excessive transferring time. Therefore, transit agencies tend to tackle this problem by coordinating schedules at transferring locations, which is combined by employing intelligent transportation systems (ITSs). Automatic vehicle location (AVL) and computer-aided dispatching (CAD) systems are used to protect transfers by holding vehicles to ensure adequate transferring times for users.

Timed Transfer System (TTS), known as Pulse System, is also a common approach used when different routes are connected at a single terminal. In a typical TTS, vehicles from all routes arrive shortly before a specific departure time and then depart together, leaving a small window of time for transferring between routes.

Expected impacts: Service coordination has a considerable impact on users' perceptions. Users usually weight transferring time 5–10 times higher than in-vehicle travel time and 2–5 times more than waiting time. In the transportation literature, this weighting is based on the difference between the actual time and the perceived time during different activities, which represents the actual value of time for users. Therefore, improving and securing transfer times will have a strong positive effect on users' perceptions of the quality of service and their future travel behavior. The main disadvantage of service coordination is related to the need for holding and delaying some vehicles (to protect transfers), which may result in extra operational costs.

Ease of implementation: Service coordination is an operational strategy, which can be implemented by transit agencies, with almost no need for involving different stakeholders. The main capital costs are related to obtaining and operating AVL/CAD systems and purchasing software that helps transit agencies in protecting their transfer. Nevertheless, most of the world's modern transit agencies already have AVL/CAD systems to monitor and adjust bus operations. Therefore, the implementation of such operational strategy can be relatively inexpensive; however, it includes extensive scheduling and planning exercises to make sure that buses can arrive at locations around the same time.

Summary and Conclusion

Planning and design for improving transit service is not an easy task that requires trade-offs between different objectives and values. Bus transit service improvement strategies are typically introduced to improve both the transit operations and users' perceptions. This chapter discussed the benefits and potential impacts of several operational and physical improvement strategies that are commonly used by transit agencies across the world. These strategies included TSP, limited-stop service, articulated buses, all-door boarding, and service coordination.

Dwell and travel times and service reliability are the key determinants of service quality, speed, and capacity. In other words, strategies that decrease travel time and improve transit service reliability (i.e., all-door boarding, reserved bus lanes, TSP) reduce operating time, recovery time, and, thereby, service cycle time. This can be translated into a reduced fleet size and/or improved headway. For existing and new passengers, this means shorter actual and budgeted travel times, with improvement in waiting times and overall comfort, which will be resulted from the increase in service frequency and reliability.

Some improvement strategies can improve only one aspect of operations that is related to travel time (TSP), service variation (articulated buses), or transferring time (service coordination), enhancing user perceptions of the service. As a role, operational strategies are usually easier to implement and acquire the required political acceptance compared to physical strategies. However, both types of strategies are required to be reviewed while assessing the local context. Trade-off between capital and operating costs is essential to be considered too while estimating each strategy cost and benefits. Overall, these strategies will help cities in achieving their broader sustainability and equity goals.

Introduction

This article describes the main points of creating livable and complete streets for active travel. It begins by discussing the key principles and knowledge of the street ecology such as the need for humane speeds, vehicle throughput efficiency at lower speeds, and the broader frameworks about walkability, bikability, and street livability. It then builds on this discussion to provide practical guidance on the design and creation of livable and complete street for active travel.

Designing for the Needs of Pedestrians and Bicyclists

For well over half a century, transportation and land use planning in the United States has been driven by automobile needs.¹ Therefore, creating walkable and bikeable communities requires a coordinated, consistent, and comprehensive approach. The “Es” needed to effectively promote walking and bicycling are *engineering* (of planning and building facilities), *enforcement* (of laws related to safe driving), *education/encouragement* (of all roadway users, including motorists, pedestrians, and bicyclists), and *encouragement*. To these should be added *evaluation*, or the measurement of conditions for pedestrian and bicycle travel, and *equity* to ensure that all actions are not only fair, but also try to overcome past harms. Thoughtful urban design and land use planning—including zoning, subdivision ordinances, design guidelines, and project review—are also essential to creating walkable, bikeable, and ultimately more livable streets and communities.²

¹ Some of the most vocal initial advocates for improving U.S. roads were bicycling organizations, active around the 1890s. A good reference for how city streets in the United States were transformed from being truly multimodal to being dominated by automobiles, or “motordom,” as it was called by Peter Norton, *Fighting Traffic: The Dawn of the Motor Age in the American City* (Cambridge: MIT Press, 2008).

² During a 2006 expert panel discussion on what makes a community “great,” there was unanimous agreement with University of Michigan professor Douglas Kelbaugh’s suggestion that they be safe and comfortable for all nondrivers.

Figure 1 Fatality risk for collision speed, by crash type. Source: Offer Grembeck based on Wramborg, P. 2005. "A New Approach to a Safe and Sustainable Road Structure and Street Design for Urban Areas." Paper presented at 13th International Conference on Road Safety on Four Continents, Warsaw, Poland, October 5-7.

Street Safety and Livability

Starting in the late 1960s, Donald Appleyard championed the idea of street livability, finding that decreasing the volume and speed of traffic enhances residents' sense of comfort and actually encourages them to spend time in front of their homes, socializing and building stronger communities (Appleyard, 1981; Appleyard and Appleyard, 2020; Appleyard and Smith, 1981; Appleyard, 2006) (Fig. 1).³

Need for Humane Speeds

We should pause to ponder why fatalities increase dramatically going from 20 to 30 mph (about 5-8 times according to some studies). After presenting this research at a number of workshops, a theory posed by a neurosurgeon sticks out as a plausible explanation—we humans, as a species have likely evolved to withstand head trauma at the fastest speed at which we can run—about 20-25 mph. If so, why not argue for speed limits on the basis of our own physio-biological limits, rather than some preconceived notion of the requirements of automobile machinery and their drivers? For example, we should not let things like the 85th percentile rule drive speed limits to be determined by the highest speeds of the 85th percentile of drivers. Instead we should allow people to set and enforce lower speeds that support a desired level of street livability.

In the future we should consider limiting the speeds of autonomous vehicles in urban areas wherever pedestrians are present, and desired to be, to 12 mph, and corridors accessing them to 20 mph, optimizing street comfort and livability for all. On shared streets and woonerfs, vehicles should be governed to travel no faster than an adult or child casually walks, which can be between 2 and 3 mph.

Speed and Vehicle Throughput Efficiency

An additional advantage to keeping speeds low is to more efficiently accommodate the number of vehicles that can pass through an area (AKA "vehicle throughput"). According to a study by Michael Li, "The Role of Speed-flow Relationship in Congestion Pricing Implementation with an Application to Singapore", found that the greatest amount of throughput can occur at relatively moderate traffic speeds at about 48 kph (or about 30 mph). In short, there is little capacity advantage to designing our streets for higher speeds. So for reasons of street livability and traffic efficiency, we should keep speeds low in urban areas (Fig. 2).

Moreover, as speeds decrease, drivers are not only better able to see pedestrians and cyclists who are immediately in front of them, but are also more readily able to stop in time, and within a shorter distance, to avoid a collision. And safer streets make it easier and more attractive for people to engage in activities that will also increase their physical and creative health.

[https://doi.org/10.1016/S0191-2615\(01\)00026-1](https://doi.org/10.1016/S0191-2615(01)00026-1).

Streetscapes That Encourage Walking

The kinds of streetscapes that encourage walking also appear to contribute to traffic safety: Eric Dumbaugh found that beautifying streets with “livable streetscape” elements, such as buildings with visually complex façades (often historic buildings) built close to the street and trees planted along the street (which, to many traffic engineers, decreases *automobile* safety), actually cause drivers to drive more carefully, thereby increasing the street’s safety for nondrivers (Dumbaugh, 2005).⁴ And through his research, Peter Jacobsen concluded that there is “safety in numbers”: collision rates decline as the number of pedestrians and cyclists present increases (Jacobsen, 2003).⁵ Drivers apparently travel with more care when they expect people to be on and around the street, so streets with street life and activity are safer than those devoid of it, leading to a virtuous cycle of street livability.

Choosing to Walk or Bike

To successfully support walking and bicycling, a community needs to provide both physical space and connectivity. Adequate walkways, dedicated bicycle and pedestrian spaces can help encourage these alternatives to driving.

Choosing to Walk: Overcoming Distance and Time

While many factors other than recreation enter into a person’s decision to walk (e.g., car availability and parking convenience; retail, housing, and residential land use mix; urban design), the ultimate decision is determined by the traveler’s perception of distance, time, safety, and comfort (“livability”), along with the inconvenience and cost of other modes of travel (automobiles, transit service, etc.).

Important work in this regard has been conducted in by Robert Schneider in his dissertation and subsequent works developing “a Theory of routine mode choice decisions” (Schneider, 2013). In this work, Schneider breaks down mode choice decision in this way:

- 1) Awareness and availability,
- 2) Basic safety and security
- 3) Convenience and cost
- 4) Enjoyment (personal physical, mental, and emotional benefits as well as social and environmental benefits from using the mode), and
- 5) Habit.

Furthermore, Schneider notes that each of the above are moderated by an individual’s socioeconomic characteristics. For this discussion, focus is being placed on those decisions that can be most influenced by the physical design of the public realm: #2 (Basic safety and security), #3 (Convenience and cost), and #4 (Enjoyment). Of course #1, Awareness and Availability can be influenced by

wayfinding strategies, public service announcements, and other Educational and Encouragement Campaigns. For more information, see discussion of the use of the “Es”, or in Appleyard, B. (2003).

A Note on Choosing to Walk: Overcoming Perceptions of Distance by Keeping Trips Interesting

According to a 2008 study, people are willing to walk farther than previously believed—about a half mile—to reach a transit station (Weinstein et al., 2008).⁶ The average adult walks three to four feet per second, which translates to about 2–3 mph (although children, seniors, and people with mobility limitations tend to move more slowly).⁷ Moreover, studies have shown that a pedestrian’s perception of time—and thereby his or her perception of distance—can be influenced by the aesthetic quality of the experience: a street alive with activity, human-scaled buildings with interesting façades, and a sense of enclosure tends to shorten a person’s perception of time, which is likely to extend the distance he or she is willing to walk.⁸

Choosing to Bicycle: Ensuring Safety and Comfort

More research is needed to fully determine how far bicyclists are willing to travel. Until now, studies have been hampered by small sample sizes, wide variances in trip lengths, and a failure to take into account both individual attitudes and the distinct community characteristics of the built environment, although a small sample size as early as the 2001 National Household Travel Survey it was found that the average bicycle commute-to-work distance was about three miles.⁹ According to a 2014 US Census report, the average bicycle commute time is 19.3 min, and most bicycle commutes were between 10 and 14 min long.¹⁰ If anyone is bicycling about 15 mph, then this is about 2.5–3.5 miles. But with the provision of more, and better protected bicycle lanes, greenway/bicycle boulevards, and better end-of-the-trip facilities (e.g., lockers, showers, and secure bicycle-locking facilities),¹¹ in addition to the wider availability of transit-carrying capacity for bicycles, the distances that cyclists may be able and willing to travel for work, school, and other purposes may well increase (Fig. 3).¹²

Pietrucha, Marsha Nitzburg, “Field Studies of Pedestrian Walking Speed and Start—Up Time,” *Transportation Research Record* 1538 (1996): 27–38, [enhancements.org/download/trb/1538-004.PDF](https://www.enhancements.org/download/trb/1538-004.PDF) (accessed September 11, 2008); John LaPlante and Thomas P. Kaeser, “A History of Pedestrian Signal Walking Speed Assumptions,” in *3rd Urban Street Symposium: Uptown, Downtown, or Small Town: Designing Urban Streets That Work*, Seattle, Washington, June 24–27, 2007.

⁸ For more on the relationship between time and distance traveled on foot, see Peter Bosselmann, *Urban Transformation: Understanding City Design and Form* (Washington, D.C.: Island Press, 2008); Peter Bosselmann, *Representation of Places: Reality and Realism in City Design* (Berkeley and Los Angeles: University of California Press, 1998), 61; and Raymond Isaacs, “The Subjective Duration of Time in the Experience of Urban Places,” *Journal of Urban Design* 6, no. 2 (2001): 109–127.

⁹ According to the National Household Travel Survey 2001, the average bicycle commute to work distance was about 3 miles (based on a sample of only 71 bicycle work commute trips reported by respondents). Of those surveyed, the average distance for all bicycle trips was about two miles (sample of 1,851 total trips). See Federal Highway Administration, *National Household Travel Survey 2001* (Washington, D.C.: U.S. Department of Transportation, 2001), nhts.ornl.gov/download.shtml.

Figure 4 The four identified groups of cyclists (Geller, 2009; Dill and McNeil, 2016) Source: NACTO.

Choosing to Bicycle: Ensuring Safety and Comfort

While bicyclists and pedestrians have many similar needs, the greater levels of speed, momentum, and inertia characteristic of bicycle travel make it more critical for bicycle plans to recognize that cyclists have a broader range of comfort and skill levels than pedestrians. In 2005 Roger Geller with the city of Portland, Oregon, posited that there was a potentially large demand for bicycle commuting, provided that the right encouragement is given through both infrastructure improvements and relevant programs (e.g., safety education, active living, energy conservation). The study identified almost two-thirds of all commuters as “interested, but concerned” regarding bicycle commuting; these are commuters who would likely “ride if they felt safer on the roadways—if cars were slower and less frequent (Geller, 2009).”¹³

A 2016 survey validating Roger Geller’s theory (Geller, 2009) that there is a large group (about 60%) who are “Interested but Concerned” in bicycling (Dill and McNeil, 2016) (Fig. 4). This is in alignment with other studies that have shown that perceived safety presents a more significant barrier for those with the least experience in traffic; precisely the group with the greatest potential to adopt cycling for transport.

This finding is consistent with other research suggesting that perhaps the best way to get noncyclists to start cycling is to create bicycle greenways/boulevards (see Fig. 9). The bicycle boulevard/greenway concept is a local street and street network that has been modified with traffic calming devices and other controls to a comfortable street network to encourage even the most cautious bicyclist while maintaining local access for automobiles.

Creating Livable and Complete Streets and Communities

As described in more detail in *Livable Streets 2.0* by Appleyard, B. and Appleyard, D. (2020), to create livable and complete streets that equitably prioritize people (pedestrian, bicyclists, scooter/skateboarders, etc.) and those who live, work, and play along streets, planners, designers and engineers should strive to achieve the Strategies, Objectives, and Tactics outlined in the **Charter for Humane and Equitable Streets**. These guiding design principles can be used for (1) understanding the nature of the problem faced by your street ecology of interests, and (2) help determine the best collection of design solutions and policies going forward. This charter, specifically the Tactical Areas, such as *getting people safely and comfortably across the street*, are used to organize the discussion below—the understandings and lessons of which have been developed and refined throughout the years of working with communities (Fig. 5).

In short, livable and complete streets and communities are created with the following components:

- Safety & Comfort that is Peaceful
- Access, Connection, and Convenience
- Aesthetics and a Positive Sense of Place that is Enjoyable
- Be Ethical, Equitable, and Just (which should be monitored on all steps, and at all times, with work to overcome past inequities).

There are then several key tactical areas to achieve the above, as follows:

- Getting people along the street, *safely and comfortably*
- Getting people across the street, *safely and comfortably*
- Slow speeds and reduce traffic volumes for *safety and comfort*
- Ecosystem thinking: design and plan from the human to regional scale to provide *access, connection, and convenience*

Some of the main components needed for overcoming distance for both walkers and cyclists, and for creating a safe, inviting, and livable walking and bicycling experience, are as follows:¹⁴

¹³ Roger Geller. The City of Portland, Office of Transportation, “Four Types of Transportation Cyclists,” portlandonline.com/TRANSPORTATION/index.cfm?a=158497&c=44597 (accessed August 5, 2008).

Figure 5 The four components of ethically livable and complete streets *Source: Bruce Appleyard.*

Figure 6 How wide does a street really need to be? We should design streets for what is needed, not oversized for preconceived notions. We should also use vehicles that are as small as possible—fire trucks need particular attention. *Source: Eran Ben-Joseph after Devon Engineering Department.*

Getting People Along the Street, Safely and Comfortably

Have you ever thought about how wide a lane for a car or truck really needs to be? when I ask my students how wide a car is, they usually say it's much larger than the average size of 6-6.5 feet. In fact, the widest a vehicle can be without a "wide load" sign is 8.5 feet (or 102 in.) (Fig. 6). We need to right size your lane widths and the numbers needed.

So why are lanes in the US 12, 13 feet, or even wider, when narrower lanes (10 foot) would work to balance both safety and livability, while still allowing cars to travel through.

In the 2000s, traffic engineer Peter Swift looked at the relationship between the physical characteristics of streets and the number of accidents. He found that the typical 48-foot-wide street had a crash rate that was 18 times higher than that of a 24-foot-wide street.

According to Speck:

"A typical American urban lane has historically been 10 feet wide, which comfortably supports speeds of 35 mph. A typical American highway lane is 12 feet wide, which comfortably supports speeds of 70 mph. Drivers instinctively understand the connection between lane width and driving speed, and speed up when presented with wider lanes, even in urban locations. For this reason, any urban lane more than 10 feet wide encourages speeds that increase risk to people walking."

So a suggestion is to use 10 foot lanes where you can—it is always good to proceed with these changes with consideration of the upstream and downstream story you are telling drivers.

Figure 7 To permit social activity, sidewalks need to be wide enough for two people to walk side by side and a third person and/or a couple to pass comfortably. In addition, sidewalks along commercial streets should allow space for seating, displays, and traffic buffers/furniture zones. It is suggested to have at least 6–8 feet so two people can walk side by side and one person or a couple can comfortably pass. In commercial zones, at least 15 feet is needed, but places can make 10 feet work, if needed. In these places, consider parklets for curbside dining. Bike lanes should be at least 5 feet, but 6 feet is preferred. Parking should be 8 feet. Avoid placing a narrower parking lane (less than 8 feet) next to a narrow (less than 5 feet) bike lane, or else you may create a “dooring” problem. *Source: Bruce Appleyard.*

Livable Walking Environments

- *How wide should the sidewalk be?* As walking should be viewed as a social activity, paths should be at least six to eight feet wide (seven to nine feet, if the walkway has a wall on one side) to provide enough room for two people to walk side by side and a third person or a couple to pass comfortably. Sidewalks along commercial streets should accommodate the interaction between a building’s activity and street life by allowing space for seating, displays, etc., as well as walkway space and traffic buffers/furniture zones, as described above. Fifteen feet appears to be a workable width; sidewalks may be even wider in areas with high levels of pedestrian activity (Fig. 7).

A note about traffic buffers: Sidewalks should be buffered from traffic annoyances (threats to personal safety, noise, etc.). Buffers can be provided by on-street parking, bike lanes, and a “furniture zone” that might include lights, signs, benches, transit shelters, planters, and/or trees.

As Speck (2018) points out, we need to recognize that “The walkable city is the rollable city, and when a city works well for people in wheelchairs, it works well for everyone”. Therefore we need to make sure wheelchairs at all times have at least 36 in. (about a meter) clearance width and directional curb-ramps at every intersection that direct people into the line of travel (not into the middle of the intersection) and that they have yellow tactile bumps for the sight impaired.

The Needs of Bicyclists Along the Street

A cyclist in motion requires width to maintain balance and to weave to the extent necessary to move forward while keeping the bicycle upright; “shy distance” is also necessary to separate the bicyclist from curbs, posts, and other potential hazards. Combining these allowances with the width of an average bicycle means that a bicyclist will need at least a five-foot-wide space to ride comfortably.¹⁵

In cases where the road is narrow, wide enough perhaps for only one bike lane, a “climbing lane” could be added on the uphill side and an in-pavement “sharrow” painted in the downhill lane to remind drivers to share the lane with cyclists.¹⁶ A “Share the Road” sign could be posted as well.

¹⁵ The space occupied by a bicycle and its rider is relatively modest. Generally, bicycles are between 24 and 30 in. wide from one end of the handlebars to the other. An adult tricycle or a bicycle trailer, on the other hand, is approximately 32–40 in. wide.

¹⁶ The incorporation of pedestrian and bicycle facilities into design and construction, originally referred to as “routine accommodation” is now commonly known as “completing the streets,” which includes a movement toward retrofitting existing streets; see completethestreets.org.

LEVEL OF TRAFFIC STRESS

Figure 8 The street design of bicycle traffic stress. Source: Alta Planning <https://blog.altaplanning.com/level-of-traffic-stress-what-it-means-for-building-better-bike-networks-c4af9800b4ee>.

Sharrows, however, should be used with caution, as research is showing they can actually be more dangerous (Ferenchak et al., 2019).¹⁷ In all cases, where possible, build separated and protected bike lanes, as research shows these can lead to overall street safety, even for drivers (Marshall and Ferenchak, 2019).¹⁸

Level of Traffic Stress: Bicyclists Need Space and Protection¹⁹

Along these lines, there have been several efforts to measure cyclist stress levels along sections of roadways (Harkey et al., 1998; Mekuria et al., 2012; Mekuria et al., 2017). Harkey et al. (1998) included such things as the presence of negative factors such as vehicle volumes, speed (as indicated by posted speed), driveways, and then positive factors such as wider bicycle lanes or paved shoulders, as shown in both the table and figure below.²⁰ Basically, bicyclists need space and protection!

LTS scores range from 1 to 4, with LTS 1 being the most comfortable for all riders, including children, and LTS 4 appealing to only the most confident bicyclists (commonly described as “strong and fearless,” who are comfortable and sometimes prefer to travel in mixed traffic) (Fig. 8).

In response, we need to develop cycling infrastructure that lowers the actual and perceived risk, and frankly stress, from traffic to attract the large number of potential riders who make up the “Interested but Concerned” group discussed above to meaningfully invite all people, regardless, gender, age, income or race bicycling abilities.

¹⁹ This section had parts adapted from Caltrans’ Smart Mobility Framework How-To Guide

²⁰ Handy and Xing identified high monthly parking costs, the social environment of the workplace and a residential preference for a good environment for cycling, a measure of self selection, as positively impacting bicycling travel behaviors (Handy and Xing, 2011).

Methods for conducting a Level of Stress analysis can be found in the paper by Mekuria, Furth, and Nixon. *Low-Stress Bicycling and Network Connectivity* published by the Mineta Transportation Institute²¹. Fig. 8 illustrates some of the LTS scores for streets with a variety of speeds and lanes. Planners can use these tables to perform a basic LTS analysis for facilities.

Bicycle Treatments: Improving Safety and Comfort for Cyclists Along the Street

Drawing on suggestions from Pucher and Dijksma (2003), who compared bicycle infrastructure improvements U.S. and Europe, the following are some design suggestions to make streets work better for bicyclists.

1. Special bicycle streets (bike boulevards or greenways) Fig. 9 which permit car traffic but give bicyclists right-of-way priority over the entire breadth of the street, with cars prohibited from rushing bicyclists or otherwise interfering with them.

A refinement of the shared roadway concept, the bicycle greenway/boulevard (as shown in the figures above and below) is a local street that has been modified with traffic calming devices and other controls to function as a through street for bicycles while placing a priority on local (over through) access for automobiles.

While some suggest 3000 ADT is OK for bicycle greenway/boulevards, I suggest carrying as little as possible and no more than 1500 vehicles a day—which roughly translates into about 150 vehicles during the afternoon peak hour, or about an average of one vehicle passing roughly every 30 seconds, which seems reasonably comfortable (greater gaps in time may occur as cars tend to platoon).

Prototypical bicycle boulevards function as through streets for bicycles while maintaining only local access for automobiles through the use of traffic calming devices that reduce car speeds and discourage through traffic. Traffic controls should be designed to limit conflicts between motorists and bicyclists and give priority to all bicycle movements. Manage traffic on bike boulevards so there are no more than 1500 vehicles a day. Some other considerations are as follows:

1. If streets are one-way for cars, make them two-way for bicyclists.
2. Create reserved bus lanes that can be used by bicyclists but not by cars.
3. Street networks with deliberate dead ends and circuitous routing for cars but direct, fast routing for bikes, including special cut-through short-cuts (Fig. 10).
4. Allow bicyclists to make left and right turns where prohibited for motor vehicles. In addition, allow bicyclists to make right turns on red, while motorists cannot (Fig. 10).

Getting People Across the Street, Safely and Comfortably

Street crossings and intersections: Safety at crossings can be cost-effectively improved through the use of signs, in-pavement markings, and clearly visible crosswalks so that drivers will proceed cautiously.²² Planners might consider ways to minimize pedestrians' and cyclists' crossing distances and exposure to traffic, and to make it easier for these travelers to see and be seen by motorists. Such improvements can be accomplished by "breaking up the task" of crossing a street with medians and islands, while "shortening the distance of that task" with curb extensions (bulb-outs) and smaller, tighter corner radii. For cyclists, a recent innovation are the protected intersections (Fig. 11).

Separated and protected intersections (see figure below) further facilitate crossing streets and making left turns. These designs greatly enhance the corners with island-separated, amply-sized refuge areas for bicyclists and pedestrians that enable them to wait far forward of the motor vehicle limit line. The refuges are shifted outward substantially so a turning vehicle can pause while rounding the corner to yield to through bicyclists and pedestrians without being rear-ended by through traffic. Bicyclists have a separate "cross-bike" area adjacent to the pedestrian crosswalk (Figs. 11 and 12).

And intersection treatments such as pavement markings, warning signs, raised crossings, and merging cyclists in advance of an intersection onto an on-street (non-buffered) bike lane have been shown to improve safety (Frank et al., 2019) (Buehler and Dill, 2016; DiGioia et al., 2017; Thomas and DeRobertis, 2013) (Fig. 13).

If you cannot create a complete protected intersection, a partial, but complementary strategy is to put in bicycle boxes—a waiting area that is clearly marked for cyclists at signalized intersections in front of waiting cars (see Fig. 14).²³

²¹ Maaza C. Mekuria, Peter G. Furth, and Hilary Nixon, *Low-Stress Bicycling and NetworkConnectivity*, MTI Project 1005, May 2012 Retrieved from: <http://transweb.sjsu.edu/sites/default/files/1005-low-stress-bicycling-network-connectivity.pdf>

²² Crosswalks in commercial areas should be at least 12 feet wide to allow people to flow in both directions. On wide streets, crossing islands with a median nose provide added protection. The clear path for pedestrians through the median island should be six feet. Countdown signals that let pedestrians know how much time they have left to cross reduce stress and accidents. See Paul Zykofsky and Dan Burden, "Walkability," in *Planning and Urban Design Standards* (Hoboken, N.J.: John Wiley & Sons, 2006), 478–480.

Providing Access, Connection, and Convenience

Providing access, connection, and convenience has as much to do with how land use activities are planned out and street networks are designed. Here are some key considerations.

- *A network of safe, direct, and comfortable routes and facilities:* A 2004 Planning Advisory Service report recommends that pedestrian (and bicycle) path connections be every 300-500 feet; for motor vehicles, they authors recommend 500-1000 feet.²⁴ For new development, these standards can be implemented through subdivision ordinances.²⁵

²⁴ Susan Handy, Robert G. Paterson, and Kent Butler, *Planning for Street Connectivity: Getting from Here to There*, PAS Report #515 (Chicago: APA Planners Press, 2004).

²⁵ The regional government of Portland (Oregon) Metro requires street connectivity in its regional transportation plan and in the development codes and design standards of its constituent local governments as follows: local and arterial streets must be spaced no more than 530 feet apart (except where barriers exist); bicycle and pedestrian connections must be made (via pathways or on road rights-of-way) every 330 feet; and cul de sacs (or dead-end streets), which are discouraged, can be no longer than 200 feet and have no more than 25 dwelling units.

Figure 15 Pedestrian bulb-outs shorten the task of crossing while empowering pedestrians to be better seen, helping them cross the street with more safety and comfort. Source: Donald Appleyard.

Creating Better Crossings

To create better crossings, consider some of the following principles. First, there are two mainly physical design principles that should be applied, as follows:

1. Shorten the Distance
 - a. Use curb bulb-outs and/make curb radii smaller;
 - b. Narrow streets by either narrowing lanes and/or lowering number of lanes;
2. Break up the Task (of crossing the street) with such things as medians and refuge islands.

Two more functional/operational principles are needed to address the informal negotiation and choreography between pedestrians and drivers:

1. Empower pedestrians to more accurately assess their own risk, AND allow them to *assert* their presence.
2. Enhance a driver's ability to anticipate and be ready to stop for pedestrians in the street.

Design Principles for Better Crossings

1. Shorten the Distance and Improve Visibility of Pedestrians by the Drivers
 - a. First, minimize pedestrians' and cyclists' exposure to traffic by *shortening the crossing distance and breaking up the task*. Some of the key measures that help achieve this are medians and islands, curb extensions (bulb-outs) and tighter corner radii.

Pedestrian Bulb-outs or Neckdowns ("Chokers")

Pedestrian Bulb-outs (Neckdowns) are devices that physically narrow the street width at either intersections or midblock. These are useful at pedestrian crossings where pedestrians wishing to cross can be better seen by motorists. They also shorten the task of crossing the street (Fig. 15).

The great advantage of bulb-outs for the task of crossing the street is they improve visual contact between drivers and human travelers (pedestrians/bicyclists)-an important component to the safety of the negotiated choreography of crossing the street. Bulb-outs essentially increase the sidewalk area at an intersection, and can also provide a location for traffic signs closer to the drivers' normal line of sight, where obstruction is also less likely to occur.

Consideration should be given to how bulb-outs can act as a barrier to a bicyclist's freedom of movement at intersections.

Importance of Urban Design and Placemaking: Qualities Believed to be Highly Correlated with Walkability

Urban design experts identified the following qualities believed to be highly correlated with walkability (Ewing and Handy, 2009).²⁶ Appleyard (2012, 2016) finds empirical evidence suggesting that these elements are indeed associated with the increased likelihood one may decide to walk or bicycle (in these cases, to access transit stations). Furthermore, research efforts testing measures of aesthetics found 25 and even 41% positive differentials in pedestrian and bicycle activity in prescribed circumstances (Heath et al., 2006).²⁷

²⁶ These measures are currently being evaluated in the field, but focus only on commercial streets.

²⁷ Heath et al. (2006) systematically explored a number of aesthetic interventions to see which factors increased physical activity. Community-scale and street-scale design factors, such as improved street lighting, adding center islands, and landscaping, were found to be the most effective.

Illustration by Bruce Appleyard

Figure 16 This figure illustrates findings from Appleyard (2012, 2016) in support of conclusions drawn from a survey of urban design experts by Ewing and Handy (2009) regarding the key urban design qualities of the street environment that encourage walking, including (1) provide a "human scale"; (2) provide a stronger sense of enclosure; (3) emanate imageability; and (4) have windows on the ground floor (transparency) and (5) detailed fenestration, emanating a visually rich sense of complexity. Source: Bruce Appleyard.

The urban form qualities important to walking are as follows:

- **Imageability** is the quality of a place that makes it distinct, recognizable, and memorable.
- **Enclosure** is the degree to which streets and other public spaces are visually defined by buildings, walls, trees, and other vertical elements.
 - For this, I suggest all buildings along a street be designed to have a relationship and connection to the street. They could have a driveway or even parking to the side—but they all need to be designed intentionally with the street in mind. In terms of enclosure, Speck (2018) points out that this enclosure is part of our desire for refuge and why good places need good edges and streetwalls to create "outdoor living rooms." He goes on to explain that "the location of those walls, and their proper height relative to the width of the space, is a subject that has been under discussion for centuries." He turns to the *Lexicon of the New Urbanism* and how "many consider 1:1—the Renaissance ideal—to be the best for streets, while, beyond 1:6 (with 1 being the building and 6 being the road), the sense of spatial definition may be lost. But he points out "even 5:1 can be lovely; think medieval Salzburg"
- Human scale is about size, texture, and articulation of physical elements that match the size and proportions of humans and, equally important, correspond to the speed at which humans walk.
- Transparency is the degree to which people can see or perceive what lies beyond the edge of a street or other public space, particularly human activity.
- Tidiness is the importance of operations and maintenance of a place and making sure that community members feel responsible for their property and community.
- Complexity is the visual richness of a place.

This list could also include measures recognizing the importance of perceptions of distance (see Isaacs, 2001) and the other measures of vitality, livability, and sense of place (see Bosselmann, 2012, Article 3).

Importance of Human Scale

Human scale urban design elements are also shown to matter to encourage walking and bicycling rates. Appleyard (2010, 2012, 2016), finds highly likelihoods of people choosing more environmentally beneficial and active human transport options (walking and bicycling) when:

- Streets are composed of buildings that are at a human scale, are located closer to the street (emanating a stronger sense of *enclosure*), have distinct characteristics such as front porches (emanating a sense of *imageability*), and providing a “visual richness” (sense of *complexity*).
- Communities are designed with narrower, well-connected streets and/or more direct walking and bicycling paths.
- When small, personal service retail opportunities are provided.

A recent definition of livable places from the US Transportation Research Board states that they are “Places where transportation, housing, and commercial development investments are coordinated to better serve the people living in those communities.”

We should recognize, however, that this is largely achieved through land use planning and urban design, primarily at a regional or subregional level of coordination. Of course this land use planning needs to be coordinated with transport investments.

Nevertheless, we should recognize that we need to start solving transportation problems through land use as well as transportation solutions—oftentimes transport professionals focus only on transportation solutions.

In his 2012 report for the German Marshall Fund,²⁸ Denver Igarta concludes that there are three key lessons to create livable streets:

1. Emphasize sojourning (opportunities to interact or linger).
2. Prioritize active transportation
3. Ensure a human scale and pace

Summary and Conclusions

This article reviewed a broad range of aspects involved with creating livable and complete streets for active travel. It began by discussing important issues facing active travelers, such the need for humane speeds, vehicle throughput efficiency at lower speeds, and factors influencing the choices to walk and bicycle. This article presented a series of overarching goals for livable and complete streets such as the need for feelings of safety & comfort; access, connection, and convenience; a positive sense of place (importance of aesthetics); and the importance of people feeling they are in an ethical, equitable, just and caring street ecology. It then built on this framework to provide a practical guide for designing and creating livable and complete streets for active travel.

Introduction

Passenger transit is shared passenger transport in which the provider of the transport is independent of its consumers. Transit is most often discussed or studied with regard to *mass transit*, or the transport of very large scales of people using high-capacity vehicles, and is usually operated in the form of *fixed route service*, in which the path of travel of the vehicle is fixed with only service frequency being scalable to demand patterns. Finally, transit in most societies is provided as *public transit*, making its operations, planning, and management subject to much public discord.

The remainder of this chapter begins with a section that discusses how transportation patterns have evolved over time with a particular focus on transit. In subsequent sections, we define different transit modes and their mode shares, transit governance practices, the management and operations of transit, transit finance, and then close with a discussion about contemporary and future challenges facing transit in light of new mobility.

Transit in the Context of Transportation History

The earliest form of transit was the horse-drawn carriage, which debuted in seventeenth century France, but did not become popularized until the 1800s. Because travel distance during this era was constrained by speed, much travel was local and central cities were especially dense. It was not until the 1890s that motorized travel, in the form of streetcar railroads, began to emerge as a serious travel mode. Like horse-drawn carriages, streetcars were operated by private companies, so fares needed to cover costs. But unlike horse-drawn carriages that used public rights of way and competed through differentiation, streetcar railroads were monopolies that owned and operated on their own tracks. As a result, while streetcar railroads provided higher travel speed and hence an ability to live further from central cities, such options were exclusive to the well-off due to the cost of the service, particularly as streetcars expanded outward from city centers. Streetcars introduced the lifestyle of suburbia, but because of transportation costs, only the wealthy typically had access to this lifestyle (e.g., Warner, 1962).

However, the combination of over-investment, limited demand, inefficient financial structures, and evolving regulation made the longevity of private streetcar railroads short (Jones, 1985; Warner, 1962). The invention of streetcars in the 1890s was a major leap in transportation technology. Investors wanted a hand in the invention and the perceived financial gains it offered, so many streetcar operations were subsidiaries of agglomerated investment enterprises that also invested in public utilities and real estate. In fact, enterprise companies began to rely on the sale of real estate along their railroads to finance their operations and maintenance. But as more and more private streetcar railroads laid tracks to get “in” on this newfound venture and revenues from tangential sources dried up, demand became spread while maintenance needs and reliance on fares increased—all at the dismay of workers who bought into the “streetcar suburb” concept. This resulted in regulatory responses, including caps on fares and demands for expanded or minimum service levels that could not realistically be fulfilled. By 1912, investor interest in streetcars was effectively

over and the subsidiary operators were left to fend for themselves—which proved infeasible (Jones, 1985). These effects were compounded by labor law changes from the 1918 National War Labor Board (NWLB) that brought about the 8-to-5 workday, thereby creating a concentrated peak period of travel that capital and labor resources had to be built to serve, but which mostly went unutilized during off-peak hours. Eventually, the only way these services could be provided to the levels demanded (by regulation) was through public ownership (Jones, 1985).

Almost simultaneous with railroads' finances turning negative, mass production of the automobile was introduced with the Ford Model T in 1913 (Adler, 1991; Wachs, 1984). Mass production of the automobile and the introduction of credit financing meant that the marginal costs of production and time to produce vehicles went down, while mass ownership became financially feasible. This compromised the monopoly that railroads had for providing long-distance travel. If that was not enough, the luxury of traveling in one's own space was alluring, so many countries constructed roads to support car ownership on the basis of that being a public interest. This especially compounded the challenge transit faced of having just a peak period of travel; what is now called off-peak travel become increasingly done by car instead of transit (Jones, 1985). Today, the automobile is not only the dominant form of travel in many western countries, but much travel depends on the automobile since transit cannot effectively serve widely dispersed trips (e.g., Pushkarev and Zupan, 1977).

Yet, public transit provides a lifeline of travel for those who are financially, physically, or otherwise impaired from accessing a car (Sanchez, 1999), as well as a policy response to increased awareness of the social and environmental impacts of dispersed travel done via the automobile (e.g., Ewing et al., 2003; Johnson, 2001; Newman and Kenworthy, 1988). Today, investment in public transit is often lauded as a way to mitigate these impacts. It, for example, provides capacity that can support density at levels that the automobile cannot (see, e.g., Table 3).

Modes of Transit and Mode Shares

Transit Mode Shares

Transit mode share is usually measured either as the share of all trips taken by transit (bus and/or rail) or the share of commute trips taken by transit (an exception is in the European Union, which tracks mode share statistics in some instances as a share of total distance by mode. See, e.g., The European Commission European Commission, 2009, *Transport in the European Union Current Trends and Issues*, March 2019, pp. 25–162. Because shares as a fraction of trips and distances are not comparable, our attention here is restricted to mode shares as fractions of trips). As can be inferred from the above historic overview, transit's mode share in the United States peaked in the early 1900s and quickly declined thereafter to become negligible today. Fig. 1 shows travel and commute mode shares in the United Kingdom and United States, respectively, from 1960 to 2010. Clearly, travel via car has increased as travel via transit has decreased. This trend represents the experience in many countries and metropolitan areas of western societies, though there are exceptions.

A focus on national mode shares for all trips or commute trips will obscure the important role of transit in larger cities. Table 1 shows transit mode share, as a percent of commute trips only, for the top ten transit commuting metropolitan areas (by mode share) in the United States.

Transit mode share varies substantially across world cities. Table 2 shows transit mode share, as a share of all trips, in metropolitan areas in selected cities. Note that major Asian and European cities in some cases move over half of all trips by transit (Seoul, Paris, Tokyo), and the share of total trips in the most transit-oriented metropolitan area in the United States, New York City, at 23%, is somewhat below the level in major Asian or European cities.

Capacity Across Transit Modes

Passenger capacity and throughput (passengers per hour) varies across different modes. Consider the general analysis from Vukan Vuchic's "Urban Transit: Systems and Technology," (2007). Table 3 reproduces information from Table 2.4 of Vuchic's book (2007, p. 76).

The peak person-per-hour capacity for a freeway lane, from 1800 to 2600 persons, agrees well with traditional highway capacity standards of 2200 vehicles/h and an average vehicle occupancy of 1.2 (for U.S. FHWA highway capacity guidelines, see p. 4 of https://www.fhwa.dot.gov/policyinformation/pubs/pl18003/hpms_cap.pdf). For data on solo and carpool commuters in Los Angeles, Schweitzer (2017) cites 2011 U.S. Census (American Community Survey) data that shows in Los Angeles 74% of workers commute to work in single occupant vehicles and 11% commute in carpool vehicles, consistent with a 1.2 vehicle occupancy rate if all carpools are two-person). The bus rapid transit (BRT) and light rail transit (LRT) frequencies from Vuchic (2007) assume frequencies that have been realized in, for example, Latin America but that go beyond what is common in many cities in the United States. The assumed BRT frequency in Vuchic is 60–300 vehicles/h—feasible, with dedicated lanes and multiple lanes of BRT. The LRT frequency is 40–60 per hour—indicative of some systems outside the United States but uncommon within the United States. The HRT frequency, 20–40 trains/h, is consistent with the most frequent service internationally, but is higher than the current peak HRT frequencies of many United States systems.

Contemporary Public Transit Governance

In the United States, the Constitution defers land use and transportation decisions to states, and states have discretion in determining how much control to delegate to municipalities. States are classified as either *local-control* or *home rule states*, in which local jurisdictions are assumed to have freedom from state government in the planning of land use and transportation, or *Dillon's Rule*

Passenger Transport by Mode from 1952 (TSGB0101). United Kingdom Department of Transport.

Notes: Travel via taxi is included in the public transit category in the United States; automobile category in the United Kingdom. “Other” includes all other recorded modes of travel, such as air, walking, and pedalcycles.

Figure 1 United Kingdom travel mode shares and United States commute mode shares (1960–2010).

Table 1 Top ten transit commuting metropolitan areas^a

Consolidated metropolitan area statistical area (CMSA)	% Commute trips by public transportation
New York-Northern New Jersey-Long Island, NY-NJ-PA	30.50%
San Francisco-Oakland-Fremont, CA	14.60%
Washington-Arlington-Alexandria, DC-VA-MD-WV	14.10%
Boston-Cambridge-Quincy, MA-NH	12.20%
Chicago-Naperville-Joliet, IL-IN-WI	11.50%
Philadelphia-Camden-Wilmington, PA-NJ-DE-MD	9.30%
Seattle-Tacoma-Bellevue, WA	8.70%
Baltimore-Towson, MD	6.20%
Los Angeles-Long Beach-Santa Ana, CA	6.20%
Portland-Vancouver-Beaverton, OR-WA	6.10%

Note: The top ten transit commuting metropolitan areas are from among the 50 largest metropolitan areas. It is unlikely that smaller metropolitan areas would have higher transit commute mode splits.

^aAmong the largest 50 metropolitan statistical areas.

Source: 2009 American Community Survey as summarized in McKenzie, 2010, Table 2, pp. 5-6, Table 4, p. 10, and Table 3, p. 10, as adapted from Marlon Boarnet, *Land Use, Travel Behavior, and Disaggregate Travel Data*, In: Susan Hanson, Genevieve Giuliano (Eds.), *The Geography of Urban Transportation*, 4th edition, The Guilford Press, New York, Table 7.1, pp. 163–164.

Table 2 Transit mode share in selected world cities, all trips

City/Metropolitan area	Transit mode share, all trips
Seoul	66%
Paris	59%
Tokyo	51%
Singapore	44%
London	27%
Beijing	23%
New York city	23%

Source: Lisa Schweitzer, *Mass Transit*, in: Susan Hanson, Genevieve Giuliano (Eds.), *The Geography of Urban Transportation*, 4th edition, The Guilford Press, New York, Table 8.2, pp. 187–188.

Table 3 Capacity for freeway lane, bus rapid transit, light rail transit, and heavy rail transit, from Vuchic (2007)

	Vehicle occupancy	Vehicles per hour	Person capacity per hour ^a
Freeway lane	1.2–2.0	1500–2000	1800–2600
Bus rapid transit	40–150	60–300 ^b	4000–8000 (low end) to 20,000 (with multiple BRT lanes)
Light rail transit	100–750 ^c	40–60 ^d	6000–20,000
Heavy rail transit	140–2400 ^e	20–40	10,000–70,000

^aPer Vuchic (2007), low and high extremes are not products of all low and high values. Vuchic argues the extremes rarely coincide. Values here are from Vuchic (2007).

^bBRT frequency high end assumes multiple parallel lanes and overtaking at stations.

^cLRT assumes 1–4 cars.

^dLRT frequency is much higher than common design capacity in U.S. systems. As an example, in Los Angeles light rail, for the Expo and Blue LRT lines, 10 trains per hour is close to design capacity.

^eHRT assumes 1–10 cars.

states, in which the state is assumed to have authority in planning land use and transportation unless explicitly delegated to a locality by law (Briffault, 1991; Russell and Bostrom, 2016). Depending on the type of state, transit boards are generally established as either an agency of the state or a local agency with corresponding authority. As a result, some transit agencies tend to have an inherent regional or state orientation toward their planning and management, while others are more locally focused.

An additional consideration is the board or governance structure of a transit agency. Many transit agencies are departments of a *general-purpose government*, like a city, county, or state (e.g., Leland and Smirnova, 2008). These are sometimes referred to as a *government department form* of government enterprise. In other instances, transit agencies are an interjurisdictional *special-purpose district*—that is, an independent agency created to fulfill a specific purpose (e.g., Leland and Smirnova, 2008). Special-purpose transit districts are usually governed (and financed) by a *joint-powers authority* (JPA), which is a shared-governance arrangement among the local jurisdictions—called member agencies—that receive service. Both types of transit agencies are traditionally governed either by all or some proportional subset of the area's elected leaders. However, transit agencies can also be overseen by a citizen appointed board, in which nonelected persons are chosen—by either local officials (e.g., Long Beach Transit (“About Us.” *Long Beach Transit*, ridelbt.com/about-us/)) or state officials (e.g., Massachusetts Bay Transportation Authority (“Leadership | MBTA” *Massachusetts Bay Transportation Authority*, <https://www.mbta.com/leadership>))—to oversee the transit agency. Less common are special-purpose transit districts that are governed by a directly elected board; to our knowledge, only three such transit agencies—the Alameda-Contra Costa Transit District (AC Transit), San Francisco Bay Area Rapid Transit District (BART), and Denver Regional Transportation District (RTD)—exist in the United States. Special purpose districts governed by specially appointed or directly elected officials are sometimes referred to as *public corporations*.

Conceptually, these different board structures subject transit agencies to different levels of politicization and constituent responsiveness (e.g., Gerber and Gibson, 2009). On one extreme, while special-purpose elected boards are more directly accountable to the public they serve, by their members being locally elected for a narrowly defined purpose, they are also more susceptible to being especially focused on parochial and special interests in transit decision-making—sometimes at the expense of at-large considerations. For JPAs and general-purpose government agencies overseen by elected officials, while board members are directly accountable to the public through the election process, they are responsible and elected for overseeing many other government functions, making their attentiveness to transit agency oversight possibly less focused and less informed compared to directly elected special-purpose boards (e.g., Hamilton et al., 1983). When they do attend to transit oversight, funding and service delivery decisions tend to be geopolitically driven (e.g., Gerber and Gibson, 2009; Wachs, 1985). In consideration of this, many suggest that a public corporation form of governance with appointed representatives is ideal because appointees can be attentive to, and well-informed

about, transit decision-making, while being several degrees removed from politics (e.g., [Hamilton et al., 1983](#)). On the other hand, by being several degrees removed from public oversight, appointed boards may be less responsive to and representative of the public (e.g., [Mitchell, 1997](#)).

There are many derivatives from these different combinations of transit agency governance formats. Among the most evident is the number of transit agencies an urban area has and their approaches to financing projects. In the State of California, for example, the nine-county San Francisco Bay Area region has 32 different transit operators (“Transit Agencies.” [511 SF BAY](#), Metropolitan Transportation Commission, [511.org/transit/agencies](#)). This creates fragmentation for a transit user seeking seamless travel, but is a product of the local control nature of the state; transit provision is locally controlled and, unless localities voluntarily form a JPA or the state legislatively creates a special-purpose district, localities fend for themselves. By comparison, in the Dillon’s Law State of New York, differently branded transit services in the New York City area—including the Long Island Railroad, Metro North Railroad, and New York City Transit—are all governed under a unified agency, the Metropolitan Transportation Authority (MTA). In addition, as of 2018, 24 counties that account for 88% of California’s population rely on local option sales taxes (LOSTs) to fund transportation, and transit receives a disproportionate share of these funds relative to its mode share ([Lederman et al., 2018](#)). However, transit funds from LOSTs are disproportionately used for capital projects, the distribution of funds are largely influenced by geographic equity interests rather than demonstrated need, and voters’ support for LOSTs rely on substantively invalid arguments that are dissociated with their potential to use transit ([Crabbe et al., 2005](#); [Lederman et al., 2018](#); [Manville and Cummins, 2015](#); [Manville and Levine, 2018](#)). These realities surrounding LOSTs can largely be attributed to the authority and geopolitical influence that different transit board structures have in a local control state. New York’s MTA, on the other hand, is governed by a board of appointees, and the MTA is not permitted by law to pursue LOST measures to finance operations or capital projects. As a result, the MTA cannot so easily turn to system expansion as a solution to demand and must find alternative ways to address such challenges.

Transit Management

Transit Operations

Transit operations emphasize either coverage or performance. Given that a principal function of public transit is to provide a transportation lifeline to those who cannot afford an automobile, many transit providers operate using the *coverage-based model*, in which routes and frequencies are determined in order to achieve maximum coverage area. Under a strict coverage-based model, transit routes tend to be circuitous and route frequencies are standardized across all routes. This contrasts with the *performance-based model*, in which routes and frequencies are defined to concentrate resources where there is demand and create a grid-based network. These models are mainly used to differentiate types of bus operations since both routes and frequencies can be easily changed in a bus environment. For rail, once the network is built, the only adjustable aspects of service operations are generally vehicle size and service frequency. Thus, from an operation’s standpoint, rail is strictly a performance-based operation.

Among the most common performance measurements in the industry are *ridership*, which is the total number of riders; *passenger-miles*, which is the sum of the miles that each individual rider travels; and *passenger-hours*, which is the sum of the hours that each individual rider travels (see e.g., [Schweitzer, 2017](#)). These measurements are often then compared to the *vehicle-miles*, *vehicle-hours*, *seat-miles*, *seat-hours*, and *labor-hours* of the transit providers to assess per unit efficiencies.

Some constraints that impact transit operations are running times, labor work rules, and system capacity. *Capacity* refers to the throughput of a system, can vary by location and time, and includes both vehicle and passenger components (i.e., *vehicle capacity* and *passenger capacity*). To identify how to allocate rolling stock and labor resources, transit operators use *load factors*, which are a measurement of how full a transit vehicle is relative to the number of seats on the vehicle ([Schweitzer, 2017](#)). A load factor of 1 means that the number of passengers on the vehicle is equal to the number of seats on the vehicle; less than 1, that there are more seats than passengers; more than 1, that there are more passengers than seats.

Different transit operators have different ways of measuring their load factors. Most bus operators use automated people counters on bus doors to derive load factors at every stop. Some rail operators assume passengers make round trips and use a common fare payment media, so use the time and station where they enter the system on two different occasions to associate them with trains, times, and locations. More sophisticated rail systems require passengers to tag in and out of the system and use this information to assign them to specific trains to determine the trains’ load factors.

When multiple routes in a system experience load factors that exceed capacity, transit operators must decide how to allocate scarce resources, such as buses and rail cars. The objective is to either mitigate or equalize the problem across all routes. Most often, this is done by calibrating system demand to identify a standard load factor that is then used to allocate vehicles. For example, if the standardized load factor is determined to be 1.2, this may result in one route having a frequency of five buses per hour and another having a frequency of twelve buses per hour, but these frequencies help ensure that both routes experience similar crush loads, given capacity and resource constraints.

A unique capacity constraint of rail is the track network. There are many rail systems where two or more rail lines converge into a single rail line, which creates a capacity constraint for all train routes that use the shared segment. While, for example, the shared rail segment may be able to serve a train every two minutes, if five branch lines converge onto the shared line, they are each limited to an average throughput of one train per ten minutes. The most common way this is mitigated is by building multiple sets of track in the respective area(s), which requires extensive real estate.

Negotiated labor contracts and route run times have overlapping impacts on operations. The *run time* of a route is the amount of time it takes to travel from one end to the other. Most labor contracts have multiple provisions that limit the amount of work that frontline workers can do without a break or lunch. At the same time, transit operations managers need to ensure that routes run on a standard frequency and also have an interest in defining routes that are optimal for transit users. It is not uncommon for work rules, route runtimes, and route frequencies to not align, resulting either in workers receiving extended breaks or optimal routes not being implemented. A common method of overcoming this dilemma is through *interlining* routes, wherein multiple routes terminate at a common terminus, and a vehicle and/or its operator arrive under one route but depart as a different route. This allows a transit provider to maintain a standardized frequency on the different routes without having to provide longer than reasonable break periods—however long “reasonable” is. However, a drawback of this practice, particularly with bus operations, is that it can divide routes up at the expense of seamless travel for riders.

In addition, the transit sector is well-documented as a sector where frontline worker earnings have outpaced other industries of similarly skilled workers. In the United States, although federal and state transit operating subsidies have tended to be justified on the basis of maintaining or increasing service quality to compete against the automobile, operating costs have increased while both labor productivity and service quality have decreased—suggesting subsidies have not gone to maintain or improve service, but to increase labor earnings. Wachs (1989), referencing Pickrell (1986), shows that, between 1965 and 1983, after controlling for inflation, transit operating costs per vehicle-mile increased 80%. This increase paralleled the transition of transit operations from private to public; whereas the share of transit vehicle-miles of service that were publicly operated in 1965 was 48%, it was 96% in 1985 (Wachs, 1989). More recently, Morales Sarriera and Salvucci (2016) similarly found that transit workers in the United States received pay and benefit raises that greatly exceeded the rate of earnings growth in similar sectors, even while productivity has remained relatively stagnant. Some (e.g., Jones, 1985) suggest that this is caused by outdated labor management practices that lead to few promotional opportunities, leaving only wage increases as a viable way to increase workers’ annual earnings.

Finally, transit operators must consider fares. In the United States, effectively no transit operator sets fares that cover even half the cost of providing service (Schweitzer, 2017). While private transit companies used differential fares to price different lengths and travel times based on demand and costs, public transit services, particularly in the United States, generally do not differentiate fares. The migration to flat, undifferentiated fare structures increased sharply in the 1970s and many studies have shown that this facilitates cross-subsidies from short-distance riders to long-distance riders, off-peak riders to on-peak riders, and lower income populations to higher income populations (e.g., Brown, 2018; Cervero, 1981; Oram, 1979). These practices and outcomes are particularly true of bus operators. One reason for this is that flat fares are simpler to implement and manage. Most transit operators that have differential fares operate rail and either have computerized systems to account for the fare differentials and charge accordingly, or on-board conductors who validate fares. The implications these practices have on financing are discussed later.

Capital Project Planning

Another element of transit management is the planning and implementation of capital projects. A *capital project* is any project that involves the building of new infrastructure, including the replacement or upgrade of existing infrastructure.

Capital project benefits are generally classified into one of two categories: transportation effects and expenditure effects (Taylor, 2017). A *transportation effect* is usually long-term and pertains to the benefits the infrastructure project will have on travel and its residuals. Congestion relief, reduction in air pollution, faster commute times, or a more pleasant travel experience are all transportation effects of transit capital projects. *Expenditure effects*, on the other hand, are generally short-term and pertain to economic or other localized gains, not from the infrastructure itself but from the expenditure of money to build the project. Common examples of expenditure effects include the creation of local jobs for construction and, relatedly, increased local economic spending resulting from the increase in workers, and income in the project area. Both benefits are leaned on to politically advance capital projects, though only transportation effects are an economically effective reason to pursue them because they are the only benefits that are directly germane to the investment (Taylor, 2017).

Even so, transit capital projects are often oversold on their benefits, underdelivered in time, and underestimated in their costs (Flyvbjerg et al., 2003). A review of the 1970s’ resurgence of rail in the United States offers a good illustration of this and why this occurs (Pickrell, 1992). Eight rail projects of the era—in Atlanta, Buffalo, Miami, Pittsburgh, Portland, Sacramento, and Washington, DC—averaged being eight years behind schedule, which contributed to each project’s capital costs being much higher than projected due to inflation. In addition, operating expenses of projects averaged 38% higher than projected, and ridership modeling was positively biased during planning phases. These deficiencies in the performance of system expansions can generate or compound *core system impacts*, which are any adverse impacts posed upon pre-existing services that is caused by an expansion project. Among other examples, trains and buses may experience crowding earlier along the route than before, resources may be redistributed away from existing services to accommodate the new service, and added wear and maintenance demands are placed onto the system.

Transit Finance

Transit budgets generally fall into two categories: an operating budget and a capital budget. A transit agency’s *operating budget* covers day-to-day, recurring costs of operations, such as the labor costs of mechanics, bus and rail operators, and administrative staff. *Capital budgets*, on the other hand, cover the short-term costs of technical contract staff and construction labor associated with the development and implementation of capital projects.

Table 4 Comparative Farebox recovery ratios

<i>Transit agency</i>	<i>Country</i>	<i>Type of service</i>	<i>Fare structure</i>	<i>Farebox recovery ratio</i>
Mass Transit Railway (MTR)	Hong Kong	Heavy rail, light rail, bus	Distance-based	124% ^a
San Francisco Bay Area Rapid Transit (BART)	United States	Heavy rail	Distance-based	70% ^b
Transport for London	United Kingdom	Heavy rail, bus	Zonal	72% ^c
Calgary Transit	Canada	Light rail, bus	Flat	45% ^d
Metropolitan Atlanta Rapid Transit Authority (MARTA)	United States	Heavy rail	Flat	33% ^b
Los Angeles County Metropolitan Transportation Authority (LA Metro)	United States	Light rail, bus	Flat	19% ^b
Santa Clara Valley Transportation Authority (VTA)	United States	Light rail, bus	Flat	10% ^b

Because transit services cannot be self-sufficient in most areas of the globe today, their operations are inevitably financed through sources other than fares. Transit operators use *farebox recovery ratios*—the quotient of the revenue generated from fares divided by the operating costs of the service—to measure their cost efficiency. A ratio of 1 (100%) means that the operating costs are equal to the agency's farebox revenue; less than 1, that the agency's operating costs exceed the revenue generated through fares; greater than 1, that the agency is generating more through fares than it is expending on operations. **Table 4** illustrates that the vast majority of transit providers across the globe operate at a loss when only farebox revenues are considered. Asian-based rail providers stand out as the main exception. While some of the differences between operating costs and farebox revenues are made up through nonpassenger sources of revenue, such as the rent or sale of advertisement space or real property, these sources are historically not enough to balance the budget. The differences between operating costs and operating revenues are most often funded by local, state, and federal taxes.

Unlike operating budgets whose sources and costs are recurrent and predictable, and whose costs can be scaled to match total funding, capital costs are none of these. When a transit agency decides to invest in a capital project, it must both determine the costs of the project and identify one-time sources to finance the projects. Very often, capital projects experience cost overruns and delays (Flyvbjerg et al., 2003; Pickrell, 1992). When this occurs, transit agencies must identify additional one-time sources of revenue to bridge the gap in capital financing. One-time sources of capital funds usually come in the form of competitive grants from state and federal governments, as well as through local taxes, like sales tax or bonds financed through property taxes. Oftentimes, the sunk cost of how much has already been invested in a project is used to bargain for additional funds from financiers. Dubbing a *commitment trap*, rather than ending the construction of a halfway built project, the tendency is to give the money necessary to complete the project (Schweitzer, 2017). This reality carries on into operations, even if the ridership volume falls well short of what was estimated, thereby requiring additional operating subsidies to cover the costs.

Public Financing

Funding is the primary mechanism through which higher levels of government that defer authority to lower levels of government nevertheless influence transit operations and planning. By setting conditions for which funds will be allotted, higher levels of government are able to impose how transit is operated and planned. In the United States, for example, transit operations are partly influenced by Title VI of the Civil Rights Act of 1964. Under this act, any transit operator who receives federal funding must conduct disparate impact and disproportionate burden studies for any fare or operating change in order to ensure that protected populations are not adversely affected by the changes compared to other groups. A *disparate impact* occurs when a face-neutral change results in a community of color being adversely affected relative to other racial groups, while a *disproportionate burden* occurs when low-income populations are negatively affected relative to other income groups. Central funding agents that receive and allocate federal funds to capital projects, like metropolitan planning organizations, must also demonstrate that their method of funding capital projects does not disproportionately short change low-income or racial minority populations. There are also many other federal rules and acts that transit operators must abide by as a condition of their receipt of federal funds, such as how they provide paratransit service in accordance with the Americans with Disabilities Act (ADA). While operating funds come with many conditions attached to them and their distribution is subject to political discourse, they are mostly dispersed based on defined and persistent formulae.

Because capital project costs generally far exceed what can be financed through local resources, transit agencies rely on state and federal funding to complete local capital projects (Taylor, 2017). While this is also true for operations, finance for operations is able to be established by a recurring formula, so is not as frequently subject to political discord. By comparison, each time that a new capital project seeks financing, it is subject to political debate about how to divide up a limited amount of funds across multiple projects. As a result, rather than capital project financing being allocated based on some measurement of need—for example, where

the transit investment would generate the most use—they are allocated based on political bargaining. The often-parochial focus of transit financing exacerbates this. As an example, even though the New York MTA's ridership accounts for over a third of transit ridership in the United States and this magnitude in share has not changed for decades, transit capital investments over the past several decades have focused on cities with markedly less transit ridership.

To be sure, there are federal, state, and regional financiers of capital projects whom have competitive review procedures or build conditions into their financing programs—for example, that the “requesting agency” demonstrates strong transportation effects of their project using approved methods. However, general fund allocations are not subject to this, are most often a part of the financing of any mega capital project, and are much more geopolitically determined. In addition, the methods that requesting agencies are expected to use to legitimate a project are able to be undermined using biased inputs that generate positive results (Flyvbjerg et al., 2003; Pickrell, 1992; Wachs, 1990). Once funds are allocated, whether competitively or politically, it creates the aforementioned commitment trap for higher levels of government. In many respects, transit agencies in local-control states, when they have passed a local financing measure for a capital project, have an advantage because they have already committed so much to the project themselves and can use this in their bargaining.

Thus, while higher levels of government influence projects and operations through financial conditions, they tend to also bear the risk of any capital or operating cost overruns associated with a project. Some suggest that, if this risk was placed on the local agency advancing the project instead, it would improve the quality of projects that seek funding from higher levels of government (Flyvbjerg et al., 2003; Pickrell, 1992). In other words, the commitment trap enables poor capital project planning.

Other Considerations

While transit in the United States is financed almost exclusively through a combination of farebox revenues and local or state taxes (for operations) and a combination of federal, state, and local taxes (for capital construction), other models are possible. Most notable is the use of land value capture in some Asian countries.

Hong Kong is possibly the best example of land value capture in transit. The Hong Kong Mass Transit Railway (MTR) was formed in 1975 and is the mass transit rail authority for the Hong Kong special administrative region (SAR). Due to its British colonial heritage, the government of the Hong Kong SAR owns all lands within the region. The Hong Kong SAR government is the primary stockholder in the MTR, which is a private company. Beginning in the 1990s, the Hong Kong MTR and the Hong Kong SAR government developed the “rail + property” model of rail transit capital finance. Lands above and near future stations are granted to the MTR by the Hong Kong government, and MTR then plans, constructs, and operates the rail line and engages private developers to build developments near stations. The difference between the pre-rail land value and the after-rail land value accrues to MTR via development agreements, and is used to finance MTR rail line construction (Suzuki et al., 2015).

This approach is commonly called land value capture. Rail transit, by producing a land value premium (through improved access), increases land value near stations. Using that increased land value to finance rail transit was not uncommon in the United States before World War II (Bernick and Cervero, 1997) but is rare in the United States now. Land value capture is more common in Asia, and the method described in Hong Kong is similar to land value capture methods used in, for example, Tokyo (Bernick and Cervero, 1997).

The Future

Transit is in a unique predicament today that makes its future uncertain. The rise of ridehail services, like Lyft, Uber and Didi Chuxing (China), and dockless shared bicycle and scooter services, like Bird and Lime, have shaken the transportation industry. These services have come to be known collectively as *disruptive transportation technologies*. It is clear that overall transit ridership has fallen in parallel with the rise of disruptive transportation technologies. After experiencing ridership and mode share growth for several years following the 2008 recession, both measurements of transit utilization have been on the decline since 2015 in the United States (Graehler et al., 2019; Manville et al., 2018; Taylor et al., 2019). These changes coincide with for-hire transportation—inclusive of traditional taxicabs and limousines, in addition to ridehailing—doubling in use since 2009, which is reasonably attributable to the onset of ridehail services (Conway et al., 2018).

A lot of current research is seeking to explain this decrease in transit ridership with a particular focus on disruptive transportation technologies. While there is a clear correlation between the introduction of disruptive transportation technologies and the fall in transit ridership, the causal relationship, if any, is unknown, as of yet. For example, whereas Hall et al. (2018) suggest that ridehail services complement rather than substitute for transit trips, which would suggest that the decline in transit ridership is explained by other factors; Doppelt (2018) and Graehler et al. (2019) suggest that ridehail services are a substitute for transit, but that their substitution effect is a function of time since the services' penetration into the given city. Other research suggests that there are mixed results, including that ridehail services are initially complementary of transit but become substitutive as they penetrate the local market (Nelson and Sadowsky, 2017), and that the services are substitutive of local transit services but complementary of heavy and commuter rail services (Clewlow and Mishra, 2017; Grahm et al., 2019; Graehler et al., 2019). Dockless mobility services are still too new for much to be known about their impacts.

At the same time, it is well documented that none of the disruptive transportation technology companies have made a profit since their inception. In fact, they have all relied on heavy venture capital investments to subsidize their services. Thus, all of the aforementioned research findings on the use of disruptive transportation technologies, as well as any associated effect it has on transit use, are artificially inflated; if users paid the full costs of the services, their use and effect would be less.

If ridehail services find a path to becoming financially solvent, the market of use will likely look much different than it does today, and it will have a different effect on transit than the latest estimates suggest. Under one scenario, these services are an impetus to a future of autonomous, all electric, shared mobility, where the costs of paying a driver are removed from the equation and the flexible service model of transit becomes more broadly adopted (e.g., [Sperling, 2018](#)). In fact, a number of transit service providers have responded by converting fixed route services into flex services. Under this concept, the unsustainable costs of ridehailing services are merely a short-term reality until autonomous and connected vehicles are fully developed. To date, however, this “three revolution” concept of a transportation future has not developed as expeditiously as promised, and many practical constraints to the vision remain, including the many engineering constraints to automating dispersed trips in multiple vehicles across multiple traffic intersections. Instead, some suggest that fixed route transit service—principally by their being fixed routes—are the best candidates of any “three revolution” future ([Currie, 2018](#)).

On the other hand, if disruptive transportation technologies do not find a financially sustainable model to exist, they will no longer exist as private companies. Theoretically, this could return public transit service and ridership back to its 2015 levels. Alternatively, if the public accepts disruptive transportation technologies as a public interest, much like how unsustainably financed private railroads and suburbanization became accepted as a public interest to finance in the early 1900s, ridehail services could conceivably be incorporated into public transit financing and service provision.

Summary and Conclusions

In this chapter, we have summarized the evolution of transit, surveyed ways that it is governed and operated, and some of the contemporary and foreseeable challenges the industry faces.

In the United States, early forms of transit, including the horse-drawn carriage and early streetcars, were privately financed and operated. However, the unsustainable financial structure of private transit providers eventually caught up to the industry. With a sizable share of the population building their life-work locations and travel around dependable transit, the financial fallout of the industry led to an increase in public oversight. Production of the car and adoption of automobile travel by the wealthy compounded the financial insolvency of the industry. In time, mass production of the automobile, the invention of credit-based financing for automotive purchases, and extensive construction of roadways made the automobile more accessible and desirable to the broader population. Today, in much of the developed world, transit mainly operates to provide a lifeline mode of travel to those who are unable to use a car or as a policy instrument for addressing harms attributable to automobile reliance.

These contemporary goals for providing transit service inform how transit is financed and operated. For example, many transit operators seek to maximize coverage area rather than service performance. In addition, in most areas of the developed world, transit’s mode share is less than 10% and fares generally cover less than 25% of the costs of providing service. As a result, public transit providers generally have to rely on alternative sources of revenue to finance both the operating and capital costs of transit services. How locally or regionally focused a transit agency is, the amount of independent authority it has, and the degree to which its board structure exposes it to geopolitical factors, can greatly influence how some of these decisions are made at a microlevel.

Among the most live challenges facing the transit industry at present is the rise of disruptive transportation technologies and the impact these have had on transit ridership, mode share, and revenues. Ridehail services, in particular, have made car-quality access without the car ownership cost, widely available. The degree and direction of impact these services have had on transit is unclear, however, primarily due to data not being available for analysis. Some studies suggest that ridehail services complement transit; some suggest that they compete or substitute for transit; and some suggest that the services complement rail transit but substitute for local transit. Notwithstanding these findings, all indications, including ridehail companies’ public financial records, suggest that disruptive transportation technology companies have yet to generate a profit, and their path to making a profit is uncertain. In other words, like private transit service of the 1890s and 1900s, disruptive transportation technology companies are so far financially unsustainable as private entities. So far, research has only illuminated the short-term impacts of these services. We are at an early stage of transportation disruption, and as in the previous era of the 1890s and 1900s, it will take time for the impact on public transit to become clear.

Introduction: Characteristics of Road Infrastructure

The word *infrastructure* is a literal combination of the Latin “infra”—what means below—and “structure.” Infrastructure is therefore an underlying structure that supports activities such as transport. Generally, infrastructure refers to the physical structure, however some authors include in their definition also the organizational structure, the institutions, and the management, linked to that hardware. Infrastructure can be defined as “all physical assets, equipment and facilities of interrelated systems and the necessary service providers, together with the underlying structures, organizations, business models and rules and regulations, which are used to offer certain sector specific commodities and services to individual economic entities or the wider public to enable, sustain or enhance social living conditions” (Weber and Alfen, 2011, p.9). Roads are by far the *most dominant form of transport infrastructure*, which is related to the diversity of road-related transport. Motorized transport—such as cars, busses, trucks, motors, mopeds, e-bikes—as well as nonmotorized modes—such as horses, camels, bicycles, pedestrians—all make use of the road network. Also, roads belong with waterways to the *oldest forms of transport infrastructure*. Already 2000 years ago in e.g. China and in the Roman empire huge long-distance road networks were built to connect the various parts of the empire—see Fig. 1. These old major roads are still visible in the current landscape and on maps [10440]. For instance, the old Roman road in Northern Italy, now an autostrada, is connecting the original resting places for changing horses that over time developed into the current major cities. Another example is the old silk road connecting Eastern and Western civilizations already for thousands of years, now revived as a new silk road as part of the ‘One-Belt-One-Road’ initiative. Here, we see a *paradox of inertia and innovation*. Existing road connections prove to *sustain for long periods* and tend to extend over time, creating fixation of socio-economic development along roads (resulting in agglomeration, urban sprawl, scarcity of space, environmental problems). Moreover, once a road is created it is difficult to “erase” it and the developments related to it. However, roads prove to be also strong *axes of innovation* and road transportation is innovating rapidly concerning road technology (smart roads, ITS), transportation (electrification, automation – CAD, 2020) and concerning the services of mobility (MaaS)—(see ERTRAC, 2019; KIM, 2018) [10420, 10422].

Another characteristic of road infrastructure is the very *dense, extensive, and interconnected network* that consists of nested subnetworks at various geographical scales such as international corridors (e.g., TEN-T and E-road networks, Pan-American Highway), national highways (e.g., US Interstate system; see Fig. 2), regional roads, and local streets, and paths up to individual buildings and houses—see also [10443, 10403, 10404]. The term ‘network’ is used in the discourse on infrastructure development as a designation for both the physical network (of e.g. roads) and the social network (of actors involved in planning and management). In this chapter focus is on the first (if referred to the latter this is made explicit). Road infrastructure serves both *long-distance and last-mile transportation* and its network density is unique, which causes car mobility to be by far dominant in the modal split globally (Banister, 2008). Road infrastructure facilitates diverse forms of transportation: *private and public transport*, individual and shared transport, as well as *persons and freight transport*, which all compete for the available traffic capacity of the road network. Because of all of this, road infrastructure is seen as an *important prerequisite for socio-economic development* of places and regions. Here the concept of *land use transport integration (LUTI)* (Bertolini 2012; Kelly, 1994; Wegener and Fürst, 1999—see Fig. 3) is instrumental: roads create better accessibility and connectivity [10402], which is a driver for (new) land uses (housing, working, recreation, facilities), which creates mobility, and the need for more road infrastructure. As a consequence, planning for roads is often closely linked to planning of area development resulting from policies for economic growth [10396]. Therefore, one can often observe that new administrations propose large road infrastructure development programs as they not only stimulate economic growth of regions and countries, but also provide directly extra work and jobs for the construction sector and indirectly stimulate the automotive sector – both important economic sectors in most countries.

Figure 1 Network of main road in the Roman Empire under emperor Hadrianus (Wikipedia, Andrein)

As a consequence, road infrastructure itself and its use (especially by car traffic) create *positive and negative impacts* that affect fundamental interests such as welfare, health, and property, which usually call for involvement of government. As these impacts are distributed unevenly amongst societal groups, issues of equity, and justice become important in road infrastructure planning (Martens, 2017; Banister, 2018; see also [10604]). Moreover, roads and their use create many *externalities*—land take, fragmentation, barrier impacts, noise, air pollution, safety issues etc.—which ask for a careful involvement of “passive users” of roads—the people who live and companies that are located nearby. The functional interrelatedness between road infrastructure and spatial regional development has given rise to more *integrated planning approaches*—so-called context-sensitive, place-based, or area-oriented approaches (Heeres et al., 2012). Such approaches aim to limit negative impacts by an integrated design and to create synergies (“win-wins”) between infrastructure and spatial development.

The road infrastructure network also has a *multilevel characteristic*. Roads connect localities and link the local scale with the regional scale, and at a higher spatial scale, roads link regions with each other thereby involving the (inter)national scale level. The benefits of better connectivity are usually felt by society as a whole at the network level and the higher scale of the cities, regions or countries—and of course at those places that have good access to the network (especially *hubs*, being the intersections of different modes of transportation). Especially the urban-regional scale is important for the socio-economic advantages of road infrastructure, this is the level of the Daily Urban System (DUS – closely related to the term Functional Urban Area, Dijkstra et al. 2019), the area around a city in which the daily commuting occurs to work (but also to education, facilities etc.); a potential outcome of a DUS is urban sprawl. However, the negative effects of the existence of road infrastructure and its usage is mainly with local individuals that live nearby. Road infrastructure can be characterized as a *common good*. To build a highway—let alone to develop a road infrastructure network—is a very expensive and time-consuming endeavor and little market parties can afford this. Also, roads are part of a network which developed after long time frames and which is used by many diverse parties, while its management is done at the network level by a single or few dominant infrastructure provider(s). Moreover, roads and their use create many *externalities*—land

Figure 3 The land use transport interaction cycle (after Bertolini, 2012).

take, fragmentation, barrier impacts, noise, air pollution, safety issues etc. —which ask for a careful involvement of “passive users” of roads—the people live and companies that are located nearby.

All of this results in extensive *planning and management processes* for road development in order to carefully allocate (the huge) budgets—that is taxpayer’s money—needed to balance in a sustainable manner socio-economic growth and environmental impacts in the various places involved, and to weigh the various interests of a diversity of societal groups. Moreover, roads are planned and delivered in in a dynamic context, which means that throughout the life-cycle of road infrastructure—plan preparation, construction, operation, and renewal—*adaptive management* is needed to deliver societal desired outcomes.

After this discussion of the main characteristics of road infrastructure, the remainder of this chapter discusses: how road planning (section “Planning for road infrastructure”) and management (section “Management of road infrastructure”) is done, the impacts of road infrastructure and their evaluation (section “Impacts of Road Infrastructure”), and the future trends and challenges in road infrastructure planning and management (section “Outlook: Future Trends and Challenges”).

Planning for Road Infrastructure

Planning can be described as the “process of preparing a set of decisions for action in the future directed at achieving goals by preferable means” (Dror, 1963). Worldwide, one can see that *national governments play an important role* in road planning. This regards not only national highway networks but also (co)financing and -developing of regional and local roads, because of the huge budgets and the planning complexities involved that often go beyond the capacity of decentral authorities. The planning of road infrastructure is *complex*, there are many fields of expertise needed (e.g. civil, traffic and environmental engineering, spatial design, ecological, economic, sociological, legal, and management knowledge), many conflicting interests, many interacting actors involved (both public authorities, private companies, civil society), at different levels, at different stages of the development and management process (see **Introduction**). Content and process have to be carefully dealt with addressing the dimensions of space, level, time, and actors in order to achieve sustainable outcomes—see **Fig. 4**. Regarding this, *different planning approaches* evolved over time, which can be seen next to each other in current planning practice.

Traditionally, road infrastructure planning has been mainly a *technical-rational* exercise, in which engineers and economists were dominant, looking for the optimal road network for the “the greater good”—sometimes coined with the term “*blue-print planning*” in which “predict and provide” and projects are central (Banister, 2008). Such planning approach—related to *Traditional Public Administration*—has been dominant in the Global North for most of the 20th century. However, the development of road infrastructure and (auto)mobility led also to more environmental impacts and awareness, and consequently to *resistance against*

Figure 4 Different dimensions of inclusive road planning and management and related approaches.

the negative impacts of road development. As a reaction to this, since the 1960s the planning process for road infrastructure has become more and more formalized (Arts et al., 2016) resulting in a structured planning process of forecasting, agenda-setting, defining goals, developing alternatives, assessing impacts, elaborating mitigation measures, decision-making, implementation, and operation. To support this process, tools and approaches were introduced in road planning such as traffic modelling, cost benefit analyses, Environmental Impact Assessment (see Impacts), which often became part of (legal) regulations—a process of *institutionalization*. As a result, information about goals and impacts were disclosed to external parties—such as environmentalists and residents—who became more and more successful in voicing their critique in the media and asking for an explicit role in the previously closed planning process. This fueled the introduction of formal and informal participation in the planning process from the 1970s onward. As a consequence, stakeholders could not only better voice their interests (e.g., environmental, local) but also were given the tools to effectuate their resistance before court—enlarging their *hindrance power*, NIMBY (Not In My BackYard). As a result, planned road projects were delayed or halted (Arts et al., 2016). In reaction to this, often new, more refined, procedures were introduced in an attempt to balance interests, enhance public participation (*participatory planning*) as well as giving (central) government instruments for final decision-making and implementation—that is to enhance government's *development power*. The latter fueling even more a process intense societal discussion, with government trying to enforce a final decision for “iconic” projects, but at higher costs, longer planning periods and often general discontent amongst all parties (Cantarelli and Flyvbjerg, 2013; Priemus et al., 2008).

To overcome this, *collaborative planning approaches* have been introduced that acknowledge that the development power for societal sensitive issues as road infrastructure is not with only one party—for example, the national government—but is distributed amongst many governmental levels (national, regional, local) as well as nongovernmental parties—interest groups, residents, and also private companies. These *institutional interdependencies* drove a shift from government to governance and from hierarchic governance to network governance and market governance (Kooiman, 2003; Meuleman 2008). During the 1980s–1990s, the role of national government was criticized, giving rise to *New Public Management* (Osborne and Gaebler, 1992) resulting in transferring tasks and responsibilities from the central government to private companies (resulting in e.g. *public–private partnerships*, see **Management**), decentral government (giving rise to *multilevel governance* approaches) as well as to the public itself (self-governance; engaged civic society). However, these new approaches introduced new (institutional) complexities—strategic uncertainty about other stakeholders’ objectives and behavior. In combination with societal challenges of climate change, energy transition, biodiversity, globalization, and social inclusion this results in deep uncertainties (see Outlook), that call for more *adaptive planning and management approaches* that address well the public values and various societal interests involved (see **Introduction**)—*Public Value Management*.

As discussed above, in many countries an intricate *system of planning procedures and processes* has been developed, which usually involves an overall arrangement for planning programming budgeting (PPB) regarding the road network development, and a more specific planning cycle for road projects—plan preparation, construction, operation, and renewal. As road infrastructure development involves huge public budgets, see **Introduction** and to allocate “tax payers’ money” carefully, many countries have a system of *planning programming budgeting (PPB)* in place that closely interacts with the (yearly) budget and account cycle of national government (Klakegg et al., 2016; Lee et al., 2013; van Geet, 2020). Usually, on basis of traffic forecasts, bottlenecks, and missing links in the infrastructure networks are detected resulting in a visioning process about what new road development is needed (see **Impact**). This *agenda-setting* process involves usually intensive negotiation between national, regional, and local government levels

and is heavily politicized—what is included in the scope and who is (co)financing future projects. In many countries the tax base of local and regional authorities is too limited to finance fully the development of roads. Usually national government is not only responsible for the national road network but also (co-)funding local and regional road networks. To implement the results of the agenda, *operational programming* is needed of projects, their budgets and timing—especially as long-time frames are involved in infrastructure development. For providing the budgets for the program, financing by other parties is often important: tolling or other forms of road pricing for road users; cofinancing by decentral authorities; loans by international development banks (e.g., the WorldBank); or private financing via public–private partnerships (see **Management**).

For developing specific sections of the road infrastructure network, a *planning cycle* is relevant that is usually laid down in regulations and procedures. The PPB process results in proposed projects that are elaborated in a *project study* involving such elements as: traffic forecasting; baseline monitoring; development of design alternatives (alignment of the route, road lay-out, preliminary engineering); assessment of environmental and social impacts; analysis of (societal and actual) costs and benefits; development of mitigation and compensation measures; reporting; public participation; and formal decision-making. Usually, government is initiator of a project study—unless a concession has been given to a market party—but the study itself is often outsourced to private consultancy firms. In most countries, (larger) road projects are (legally) subject to a formal Environmental Impact Assessment (EIA, see **Impacts**) and forms of public participation—also international development banks usually require this for providing loans. In addition to formal *participation*, open planning approaches are increasingly employed to disclose information and to involve local residents, companies, NGOs, and other stakeholders, requiring careful process management (see **Management**). The *formal decision*, giving consent to build the road, is with authorities, and for the national network often centralized to national government. In most countries such decision is open to appeal to court—where consent decisions are regularly annulled because of not sufficiently taking into account other (stakeholders’) interests. The social cost–benefit analysis (see **Impacts**) is often important to substantiate the need for the budgets, thereby providing a linkage between project decision-making and strategic planning and programming. To improve this linkage, sometimes an explorative study is done for defining the project’s preliminary scope, timing and budget, and for linking PPB-programming to individual project elaboration as discussed above. To *implement* a road project, construction activities are usually contracted out to building companies by way of procurement—see **Management**. If a road is delivered, it becomes part of the wider road network and its *operational management and maintenance*—which involves daily maintenance of the road, traffic management, and incident management. During operational stages also monitoring of traffic and environmental issues is important in order to enable ex post evaluation—although this is still not common practice (see **Impact**). Over time road capacity can become too limited, which after addressing in the PPB-process may result in a *new planning cycle of road (re)development*. As infrastructure is aging and functionality is decreasing, renovation and renewal can also become a reason for starting a new planning cycle (see **Outlook**).

Management of Road Infrastructure

Infrastructure management is about the organizing, conditioning and steering of actors, activities, and processes in such a way that policy is effectively and efficiently implemented. It may concern the management of the functioning of the road infrastructure network as well as the management of the development of a road section (see **Planning**). Tasks of a public or private infrastructure network manager are manifold and typically comprise: *network management*, i.e. keeping the mobility network up-to-date and future proof; *asset management*, i.e. keeping the physical assets (pavement, bridges, viaducts, noise barriers, information panels etc) functioning; *traffic management*, i.e. managing the traffic flow over the infrastructure (relevant regarding congestion, safety, environmental issues etc.); and *incident management*, i.e. quickly responding on unexpected disturbances of the network (such as traffic accidents, spoilage of hazardous goods, flooding because of heavy rainfall). Asset management, traffic management, incident management—as well as mobility and logistics management—need to be carefully coordinated by the network manager in order to make optimal use of the existing road capacity.

The development of the road infrastructure network itself—a new section, extension, renewal, renovation, solving bottlenecks—is typically performed by project management and often involves process management or (portfolio) program management (see also **Planning**). A project can be defined as a temporary organization designed to deliver a specific result by a subsequently phased process (Turner and Müller, 2003). In *project management* focus is on achieving goals and meeting success criteria, such as scope, time, budget and quality (see e.g. Meredith and Mantel, 2011; Kerzner, 2013). A specified scope and focus on risk management should prevent that changing circumstances will affect project performance – resulting in ‘being in control’ (Bourne and Walker, 2005). *Process management* is often used in situations with many stakeholders involved and where careful interaction is needed (Glasbergen and Driessen, 2005). It is focused on guiding the planning process by reacting flexibly to changes, by bringing different stakeholders together (authorities, market parties as well as civic society), and gaining acceptance (Edelenbos and Klijn, 2009; de Bruijn and ten Heuvelhof, 2002). The increasing influence of the environment on projects (see **Planning**) and the increasing influence of projects on their environment (see **Impact**) makes that projects do not stand alone and should be managed in a more interactive way. The traditional (closed) way of project management, focusing on the efficient realization of project objectives, gradually shifts to process management, interactively developing projects with their environment (Heeres, 2017). To provide a framework for strategic direction to a set of projects, portfolio programs are used so that in combination projects can deliver higher order objectives or win-win’s (Pellegrielli, 1997). In such *program management* various projects, project stakeholders and related activities are coordinated in order to realize benefits that could not be obtained where projects are implemented separately

Figure 5 The public road infrastructure value chain (after Leendertse and Arts, 2020).

(Busscher, 2014; Pellegrinelli, 1997). Program management can be seen as a response to the fragmentation caused by ‘projectification’ (Buijs and Edelenbos, 2012). Sometimes related projects are combined and managed on two levels, the program level to gain synergy and address overproject objectives and the project level for efficient output realization (Turner and Müller, 2003).

Following New Public Management (see **Planning**), road infrastructure management has been “projectified” (Buijs and Edelenbos, 2012; Busscher, 2014; Maylor et al. 2006) to a large extent, with a strong focus on efficiency in the realization of projects and involvement of market parties thereby. Projects are linearly (and technocratically) organized (Leendertse and Arts, 2020—see Fig. 5), which means that the individual planning stages are successively run through following strict protocols, with each phase building on the outcome of the previous phase. Management is thus strongly focused on control. Central for control and an important tool of project management is *risk management*. Here a risk can be seen as a probable event with a possible negative effect on time, cost, scope or quality. Typical risk management involves the identification and quantification (probability * effect), the establishment of risk management measures, the implementation of these measures and the regular evaluation and updating of the measures (see **Impact**).

In infrastructure development private companies are usually involved in preparing project studies, construction and maintenance of the infrastructure, which has to be done carefully considering the major societal interests and budgets involved (see **Planning**). As a consequence, an important part in project and program management is the management of market parties’ involvement—that is *procurement and contracting*. Procurement and contracting are part of private law, while in most countries planning procedures are part of public law. A careful link between both proves to be often complicated but also essential for delivering societal ambitions (see e.g. Lenferink et al., 2012). Public authorities are bound by (international and national) procurement regulations, based on equal treatment of potential market suppliers (“level playing field”). Procurement is thus very strictly regulated in most countries (Leendertse and Arts, 2020). In an *open procurement procedure* any interested market party can, as reaction on an announcement, register. The registrations are then tested for exclusion criteria, suitability requirements, terms of reference and awarding criteria. The tender ends with a winner who is awarded the contract. In a *restricted procedure* a preselection of interested candidates is added at the beginning of the procurement procedure. In order to stimulate a bidding market party—a private company or consortium of private companies, as projects can be very large and involve many expertise fields—to think creatively about the societal challenges involved, new forms of procurement procedures have been developed (Lenferink, 2013). These procurement procedures can only be used in special cases, such as the *negotiated procedure*, in which after tendering the contracting authority can negotiate with one or more tenderers and/or the *competitive dialogue*, in which a dialogue is held with the candidates on the framework of the tender. A special procedure is the *prize competition*, which may be an open or restricted procedure with award by means of judging by a jury. The procurement process ends with the awarding of a contract to the winning bidding consortium.

In order to accommodate the complexity of a project and dealing carefully with the interests at hand, various **contract forms** can be seen in the road infrastructure construction sector. The **build contract** is the traditional contract model for construction projects—see Leendertse and Arts (2020). The responsibility of a contractor is solely to build in accordance with the specifications of the request—provided by the authorities—called the client. A variant is the *engineer & build contract*, where the contractor has to do basic engineering of a by the client provided design. In a *design & build contract* (or design & construct) no specified design is provided by the client, only a desired outcome is presented. The essence of design & build is that a “functional space” is provided, within which market parties are allowed to search for solutions themselves. The solutions must meet the minimum quality level and must deliver the requested functions as specified by the functional specifications. Often within the functional space, direction is given through an incentive scheme about prize/quality such as *Most Economical Advantageous Tender (MEAT)*. This tender criterion enables the contracting authority to take account of criteria that reflect qualitative, technical, and sustainable aspects of the tender submission as well as price when reaching an award decision.

In line with the *New Public Management*, since the 1980s, more and earlier involvement of market parties has been stressed in order to enhance efficiency of road infrastructure (project) delivery, resulting especially in the introduction of *public–private cooperation (PPP)*. Starting with the so-called Private Finance Initiative in the UK many countries followed introducing *Design, Build, Finance, and Maintain (and Operate) contracts*. The essence of these contracts is that private capital is used to (pre)finance public infrastructure. The private consortium delivers infrastructure (or even operates it) in return for a fee over a relatively long period

(25–50 years), which fee is related to the quality delivered. The fee enables the private consortium to pay back the loan to the lenders (banks and other financial organizations). Through the “shadow of the banks” the private consortium is stimulated to deliver the required quality. In these type of contracts not only tasks—to enlarge the functional space for optimizing the (development of the) road infrastructure—but also risks are transferred to the private consortium. Since risks are rather high in infrastructure development leading to a high-risk exposure of the construction sector, this has lately led to an intense discussion about the desirability of these kind of contracts (Leendertse and Arts, 2020; Verhees and Arts, 2016). More recently, in many countries a trend can be seen to go back to the more traditional way of procurement through design & build contracts separated from maintenance, operation and finance, where the public authorities (re)take the majority of risks and effects of uncertainty. This provides also room for addressing (broader) public interests and values of the area adjacent to the road—*Public Value Management*.

This trend is reinforced as road projects and their contexts are becoming more *complex* through the increasing interaction with, and dependency, on the project’s environment and stakeholders. As a consequence, uncertainties are larger; complex systems are *less predictable and are sensitive for changes*. Moreover, the world of infrastructure and spatial development is increasingly dynamic (see **Outlook**). For instance, smart mobility and data and information technology may alter the role of the traditional road infrastructure manager and the traditional road. Smart Mobility concerns a wide range of ‘smart’ initiatives and measures to address control of travel speed, accessibility and mobility in general. It includes specialized applications in vehicles, mobile apps and mobile services (Mobility as a Service, MaaS), behavioral influencing measures, organizational measures, smart infrastructure and measures to increase the flow and capacity of infrastructure (traffic and mobility management). New market parties offering new mobility products require new relationships between market, user, and road infrastructure manager. The different Infrastructure networks and different forms of mobility will be increasingly connected by integrated efficient transfer hubs which makes them mutually dependent. Climate change, sustainability, and the energy transition might have enormous impact on our road infrastructure. However, there is little no certainty about the magnitude and even the direction of development. As a response to this increasing uncertainty and dynamism, enhancing *adaptivity* in planning and management is seen as a way forward in both practice and scientific literature (Rauws and de Roo, 2016; Skrimizea et al., 2019; Zandvoort and Willems, 2017). Adaptivity can be described as the capacity of a system to manage adjustment to changed situations, whereby the core function, the ultimate goal of the system, remains intact (Folke et al., 2010; Walker et al. 2004). *Adaptive management and planning* of road infrastructure have the ability to generate alternative solutions when the context changes (variation) (see also Holling, 1978; Axelrod and Cohen, 2000).

Impacts of Road Infrastructure

Road infrastructure has brought economic development in many cities and regions. At the same time ecological and social impacts are involved. Only a balance between social (“people”), ecological (“planet”) and economic (“profit”) impacts will result in truly sustainable infrastructure (and its usage). In general, economic and social impacts concentrate on human beings, while ecological effects merely focus on ecosystems (Geurs et al., 2009). Furthermore, economic impacts are often analyzed at the macro level of countries and regions, whereas social impacts are examined at the individual and group level on a local scale (Geurs et al., 2009). Regarding impacts we make a distinction here between the effects of infrastructure construction and use (Fig. 6).

Infrastructure has often been seen as a necessary condition for (regional) *economic growth*—see also [10396]. Historical examples include the construction of railroads (e.g., Wang and Latham, 2001) and the highway system—for example the Interstate Highway System in the USA, initiated by the Eisenhower Administration in 1956 (see Fig. 3)—which led to enormous travel time gains and connected new areas. Costs of transporting goods for instance fell by as much as 95% during the 20th century (Glaeser and Kohlhase, 2004).

The *construction of infrastructure* has direct temporary effects on labor in the construction sector. However, structural labor effects can also be discerned and relate to the operation and maintenance of roads. *Infrastructure usage effects* on the short run relate to travel and environmental hindrance due to construction works. After completion, however, travel time gains occur, which convert into

Figure 6 Impacts of road infrastructure and its usage.

economic impacts by increased productivity, employment, firm relocations, and increasing office prices. For people, these accessibility benefits result in higher incomes, a higher productivity and also in increasing house prices.

Theoretical microeconomic models from the 1960s link transport infrastructure to consumer and producer location behavior (e.g. Alonso, 1964; Muth, 1969; Wingo, 1961) and suggest that *location decisions* of firms and individuals are largely based on transport. However, a growing body of empirical studies (see Melo et al., 2013) in the last decades indicate that the relationship between infrastructure and economic development may not be as high as traditionally expected (i.e. “the law of decreasing returns to scale”; Bruinsma, 1995). Generally speaking, at a reasonable infrastructure level, transport development serves as a growth supporter rather than a growth generator (Banister and Berechman, 2000).

Infrastructure creation and usage also have *social impacts* (Geurs et al., 2009). Examples of the former include relocation (from land), destruction of buildings and cultural heritage artefacts, barrier effects, noise nuisance due to construction works, traffic hindrance, and related safety issues. In a structural way, road infrastructure influences visual quality and may result in community fragmentation. Infrastructure usage has both positive and negative impacts. From a positive side infrastructure has a direct impact on accessibility of activity locations, which gives the opportunity to develop and increase personal wellbeing (better accessibility to work, education, health, shopping, and other facilities, to family, friends, social networks). However, more indirectly transport causes *external effects*, which road users often do not fully take into account in their decision processes. On a national and global scale, these include climate related greenhouse gas (GHG) emissions such as carbon dioxide (CO₂). On a local level road use influences traffic safety and leads to noise, vibrance, and air pollution (van Wee et al., 2013), all of which result in stress, livability, and health issues. These local impacts are often subject to intensive debate during the planning stages, resulting in *mitigation measures* such as different routing (bypasses), tunnels, (noise reducing) porous pavements, noise barriers, speed limits (see Planning).

At the same time, many effects mentioned influence *ecosystems* (van Bohemen 2005). Roads act as barriers which fragment nature and influence wild life safety. Moreover, noise, light, soil, water, and air pollution, such as small particles, sulfur dioxide and nitrogen oxides, negatively impact the flora and fauna. The latter relates to impacts on biodiversity which go beyond the local scale. Moreover, indirectly CO₂ and other GHG-emissions cause climate change and thereby fundamentally affect ecosystems at a global scale. Measures relating to ecosystems impacts may vary from porous pavements, noise barriers, to culverts, under- and overpassages (“ecoducts”) to remediate habitat fragmentation. If ecological impacts cannot be prevented, nature compensation can be implemented by developing elsewhere comparable nature—ecological offsets (Cuperus, 2005).

Reducing traffic congestion, and thereby striving for shorter travel times, is an important reason for extending road capacity. The *societal costs* due to traffic congestion in many countries are large. However, these costs are generally speaking substantially lower than the costs related to traffic safety and the environment. For instance, the societal costs due to traffic jams and delays on the Dutch main road network, for instance, amounted to approximately €3- 4 billion in 2016. This is comparable to half a percent of the gross domestic product (GDP) of the Netherlands. However, the costs for noise and air pollution from traffic amounted to no less than €8 billion in comparison (KiM, 2016). And the total costs of road safety in the same year were even rounded up to between €13-16 billion. This is more than four times the congestion costs.

The *distribution of costs and benefits* of transport infrastructure are uneven across space and people. By improving regional connections, regional differences (e.g. in employment) may decrease but may also increase as a consequence of agglomeration. In the latter case economic activity further increases in already stronger economic regions at the cost of the “weaker” ones (i.e., “core-periphery model” by Krugman, 1998). Not only the most populous cities in such strong regions may then benefit, but also smaller towns which are part of the *Daily Urban System* (see also Planning). This relates to the concept of *borrowed size*, which occurs according Meijers and Burger (2017) “when a city possesses urban functions and/or performance levels normally associated with larger cities. This is enabled through interactions in networks of cities across multiple spatial scales”.

Moreover, effects may be *distributed unevenly* from a regional compared to a local perspective—between the central city and its surrounding rural area. Decisions about transport infrastructure are often dominated by macroscale accessibility issues and economic development of a region (Banister and Berechman, 2000; Tillema et al., 2012). However, undesirable impacts such as noise, air pollution and local traffic are particularly important at the local level (Bateman et al., 2001)—see Planning. This results in uneven social impacts for people living close to transport infrastructure without using it regularly. This relates to issues *equity and fairness* (coined as *transport justice* by Martens, 2017; see also Banister, 2018). Another example of unequal distributions revolves around public funds that are used for highway extensions. Such investments are particularly beneficial for those already using the highway, but far less for nonregular car users (Martens, 2017).

The impacts of new infrastructure projects can be evaluated at different stages of the planning cycle—before (*ex ante*) and after (*ex post*) the infrastructure realization. In planning practice, *ex ante evaluations* are often applied in road planning, whereas *ex post evaluations* are rare. Some important *ex ante* evaluation tools and initiatives can be discerned. *Social cost benefit analysis* (sCBA) has become an important decision support tool for infrastructure projects in many countries (Berechman, 2009; Heeres, 2017; SACTRA, 1999). The aim is to derive a summary indicator of all costs and benefits for actors affected. (Estimated) travel time gains of road infrastructure are the most important and quantifiable benefit component. Although sCBA also includes environmental impacts, such effects are harder to measure in monetary terms (van Wee et al., 2013). Therefore, to safeguard sustainable development also from a social, environmental, and ecological perspective *Environmental Impact Assessments* (EIA) and *Social Impact Assessments* (SIA) for large infrastructure plans or projects are applied (see IAIA, 1999; Vancley et al., 2015). According to IAIA (1999) EIA is “the process of identifying, predicting, evaluating and mitigating the biophysical, social, and other relevant effects of development proposals prior to major decisions being taken and commitments made”. It comprises the planning, design, decision making and implementation (follow-up) stages of that action (Morrison Saunders and Arts, 2004). SIA focuses specifically on the social

perspective – social inclusion, social inequality – and can be defined as the “process of identifying and managing the social issues, including effective engagement of affected communities in participatory processes of identification, assessment and management of social impacts” (Vancly et al., 2015). These assessments often make use of multicriteria analysis to weigh and compare different alternatives using both qualitative and quantitative data. EIA is regulated in almost all countries (NCEA, 2020) and large road projects are usually subject to a formal EIA procedure, in which environmental impacts of road development are assessed and measures are discussed to prevent, mitigate, or compensate the impacts. As impacts are difficult to predict because of the many uncertainties, *ex post monitoring, and evaluation*—that is after the consent decision during construction and operation—is essential to safeguard that the impacts stay within the boundaries of the formal planning consent and to facilitate *adaptive management* to implement remedial measures (see **Management**). Examples of this are EIA follow-up and Environmental Management Systems, which however are not (yet) standard practice in road planning and management (Arts and Faith-Ell, 2012; Morrison-Saunders and Arts, 2004).

Outlook: Future Trends and Challenges

Many trends and challenges are likely to impact road infrastructure planning and management in the coming decade(s). Without having the intention of being complete or exhaustive, three important and related (clusters of) trends can be distinguished: sustainability, smart (technological) innovation and spatial integration—see also [10442].

Important *sustainability* challenges of road infrastructure relate to climate change and broader environmental aspects—such as depletion of nonrenewable resources, biodiversity, environmental pollution, health, social inclusion—see also [10775]. To limit greenhouse gas emissions there is an increasing focus on the use of clean and renewable energy—such as electricity [10419] and hydrogen—which may impact refueling locations and processes. At the same time road infrastructure could be used for (local) energy generation, transportation and storage. Here one might think of for instance solar panels in asphalt, overhead electricity lines for electric trucks, windmills near roads. Such development might open possibilities for road infrastructure managers to link up with initiatives of civic society regarding local energy production (Spijkerboer, et al. 2019). Moreover, an increasing attention can be seen for mitigating air pollutants and noise hindrance such as: more strict regulations for car engines, tyres, establishing Low Emission Zones (LEZ), specific time periods in which certain vehicles allowed (or not), road pricing [10450], or stimulating a shift from car to other modes such as public transport, biking, walking. This is important as in densely populated areas road projects are increasingly difficult to realize because of growing environmental concerns. Future trends, however, do not only focus on mitigation but also on adaptation and on circular processes (i.e. reuse of materials—such as asphalt, concrete, steel—which becomes more relevant as infrastructure objects are ageing). Climate change will lead to more extreme weather conditions (e.g. drought, extreme rainfall) and to higher flood risks, which influence the availability and robustness of infrastructures. Planners will have to increasingly take account of all such impacts to maintain livability in localities and regions (see **Impacts**).

The use of *smart technologies*—such as Cooperative-Intelligent Transport Systems C-ITS—focuses on making better use of road capacity, increasing sustainability, and traffic safety—see **Management**. Examples include autonomous vehicles—see also [10400], smart infrastructures, and mobility-as-a-service (MaaS). These developments mutually interact. Autonomous vehicles are expected to communicate with each other and with the physical and digital road infrastructure (vehicle-to-vehicle, vehicle-to-infrastructure, and vehicle-to-cloud communication). The other way around, smart vehicle sensors may give information about the road condition which can be used for improving maintenance planning but may also be relevant for road pricing. In practice, however, privacy of information issues proves to be important institutional barrier for sharing such information between public and private parties. Another important trend is the gradual shift towards more sustainable multimodal travel—intermodal travel, or from “modality” to integrated “mobility” (from A to B) [10414]. This closely links to the concept of *mobility-as-a-service* (MaaS), which focuses on demand driven travel, fully facilitated via digital platforms, and real-time information [10420]. As a consequence of these innovations, new (market) parties enter the field of road planning and management (see **Management**). Growing interest in MaaS-concepts is stimulated by the development of (multimodal) *hubs*, both for persons transport (mobility management) and for freight transport (logistics).

Finally, a growing attention can be seen to *spatial integration*, with roads being an integral part of their surrounding area. This includes the integration of different transport networks via (multimodal) hubs and corridors (internal integration), but also relates to a better integration of infrastructure in its spatial environment (external integration; Heeres et al., 2012) – see **Planning**. For instance, multi-modal hub development relates closely to *Transit Oriented Development* (TOD; see Curtis et al., 2009) in which nodal and spatial quality are enhanced by employing land use transport interaction (LUTI – Wegener and Fürst, 1999; Bertolini et al. 2005, Bertolini, 2012). By an integrated planning of infrastructure and spatial development, negative environmental impacts may be prevented or undone (by more integrated design), social inequalities addressed (by carefully engaging communities) and economic synergies achieved (by optimizing infrastructure development with spatial development). Such so-called area-oriented approach may enhance the value of road infrastructure at multiple scales: accessibility at corridor level, socio-economic development at regional level, and spatial and environmental quality at local level (Arts et al. 2014; Heeres 2017; see also www.nuvit.eu, www.vitalnodes.eu, www.cedr.eu). This more inclusive focus asks for integrated area-oriented planning and management approaches with innovative governance arrangements, for collaboration between public authorities, private companies with civic society (van Geet, 2020). Such approach is not only relevant to the planning of new road infrastructure but also to enhance adaptiveness of existing road infrastructure (operation, maintenance, management) and its renewal—creating a new cycle of sustainable (re) development in road infrastructure planning and management.

Biographies

Jos Arts is a professor of Environment & Infrastructure Planning at the Faculty Spatial Sciences, University of Groningen, the Netherlands. He is also extraordinary professor at Northwest University, Unit Environmental Sciences & Management, Potchefstroom, South Africa. His research focuses on impact assessment and on institutional analysis and design for integrated planning approaches for sustainable infrastructure networks (Orcid: 0000-0002-6896-3992).

Wim Leendertse is a professor of Management in Infrastructure Planning at the Faculty Spatial Sciences, University of Groningen, the Netherlands. He is also top advisor for Rijkswaterstaat, the executive agency of the Ministry of Infrastructure and Water Management in the Netherlands. His work focuses on area-oriented infrastructure development, adaptive infrastructure management, and sustainable infrastructure (Orcid: 0000-0001-7706-1272).

Taede Tillema is a professor of Transport Geography at the Faculty Spatial Sciences, University of Groningen, the Netherlands. He is also senior researcher at KiM Netherlands Institute for Transport Policy Analysis. His research focuses on transport mobility patterns, transport innovation and transport planning. He also focuses specifically on the accessibility of, and the transport mobility patterns in, rural areas (Orcid: 0000-0001-7158-9893).

Introduction

Roads have always been organizing principles for cities. In the oldest settlements, roads grew organically based on local needs and desire lines. Over time, civilizations developed institutional capacities to plan and manage their character. While the primary function of roads, regardless of their ancestry, has always been to ease how people reach activities, be it the ability to exchange commercial goods, reach services or interact with others, advances in technology have affected changed their nature. What was once space reserved for the pedestrian morphed to space for the oxcart, then to the carriage, bicycle, omnibus, road car, and eventually the automobile. Each successive innovation created a different use and function.

In responding to quick advances in mobility innovation, planners and public officials are embarking on new era of road planning. They are being called on to more fully consider their function, which modes should be prioritized and supporting regulations. The outcomes of these decisions—how to manage and plan for roads—are rising in importance as cities tackle challenges of climate change, livability, and accessibility in cities.

The importance of understanding how roads are managed and planned is underscored by the fact that roads operate in rights-of-way which are largely fixed; expansion, reduction, or relocation is unlikely. For users of roads, they respond to policies from all levels of government. These policies send signals to favor various types of modes and how they are used (e.g., the speed of travel). As advances in technology play out and new travel modes prompt more claimants to limited street space, important questions emerge. How to move traffic, park cars, let kids play, encourage cycling, and anticipate whatever comes next yields an issue any planning textbook would easily depict as being truly “wicked.”

Consider a few of the contemporary issues with which city leaders are wrestling. Proponents of emerging technologies argue that tech-based gadgets provide revolutionary answers to urban traffic problems. Mobile phones and app-based inventions promise to deliver responsive mobility services, whatever shape those services may assume. Hive-minded autonomous or connected automobiles will inevitably increase the efficiencies of automobiles. Doing so, however, will continue to diminish the human qualities of streets and sidewalks. As long as road planning, inadvertently or not, favors personal auto mobility (Manville, 2017)—as it has in most cities for the past decades—cities will provide more of the same.

The right approach to road planning is to first recognize them as a public asset. Estimates suggest road space consumes between one-fifth and one-half of all land in cities. Any approach to design this space hinges on one’s perspective. Users of the transport system have preferences that are affected by their main mode of travel. Infrastructure providers and other interests, no doubt, have varying answers. But the transport industry is not charged with the responsibility to legislate how the road should function and what modes should or should not be encouraged to flourish. For many roads in a city, that responsibility goes to the political leaders.

Political leaders are the ones to legislate how local roads are used and the degree to which one mode is prized over others in decisions about the character of road space and how to appropriate its use. This chapter examines the complex and sometimes contradictory characteristics of mobility innovations and the rise of planning processes that shape mindsets and constrain change. We identify these processes as a major challenge in efforts to help cities move forward with, based on first principles, a future generation of public road space that prizes, above all, human-scaled accessibility.

Evolving Transport Modes

When a new transport innovation arrives, an opportunity emerges to envision how roads could or should evolve. Road designers have an obligation to consider the impact on the character of movement and rhythms within this public space. More fundamentally,

it allows the broader planning community to consider how cities regulate that space. Urban areas change incrementally as to most of their roads; they respond to demands and services that evolve with time. Regulations follow suit, accompanied by design standards.

The standards and regulations that have, for the past century, guided how roads should serve society firmly reinforce one form of mobility: vehicular travel. That was a policy decision. Changing these standards and regulations is a formidable challenge, no doubt, because planning processes and institutions are so firmly entrenched. In many respects, city leaders have lost an ability to envision roads as anything other than serving automobile. In cases where roads are redesigned, the scale of change is so small—such as a single bike lane or pedestrianized road—that the automotive status quo remains unchallenged. Losing sight of how other functions could be served restricts an ability to move on new and creative initiatives.

A main struggle currently facing city leaders is that a prevailing mindset about how road space is managed has permeated every aspect of city planning, urban design, and transport engineering. Roads are exclusively viewed as a space for car traffic. Consider, for example, a road that is temporarily re-appropriated by a city to support a neighborhood event or a *cyclovía*. City propaganda refers to these roads as closed even though during such events they may accrue more use than when they are open exclusively for cars. Residents have difficulty conceiving anything else. Politicians see little advantage to challenge the status quo. Even innovative transport professionals are quickly brought back in the fold, being reminded that, legally, it is best for cities to subscribe to current standards and regulations. The automotive mindset is pervasive. Efforts to prioritizing car movement has had profound impact in defining the role of road space and held hostage interests furthering anything else. This attention therefore affects the purpose and function of roads, their design characteristics, and role in connecting cities.

From Where and How?

We can trace the origin of how these ideas were legitimated: the development of bureaucratic management of city roads in early 20th century. Before 1900, roads were public places that served general purposes: buying and selling things, socializing—in addition to being grounds for passage. To move around, residents used whatever means of transport they considered best, including horses. Bicycles then emerged as a transformative transport innovation. Special interest groups, led by cyclists, quickly assembled themselves to improve both the quality of the roads (e.g., the Good Roads movement) and to pioneer institutional reforms for their use (Reid, 2015).

Then, the quick onset of the internal combustion engine and automobiles then monumentally changed the calculus of road users. Mixing horses with bikes, streetcars and eventually, automobiles, produced chaos. Cars were far faster and more powerful than anything prior road users had access to. Cars mitigated the need for horses which offered their own type of pollution (e.g., dung and carcasses) and were quickly viewed as the superior form of mobility. It became apparent that the interference between cars and other modes needed to be tamed.

To the rescue, new city departments of transportation were formed to address new traffic concerns. In the spirit of all forms of governmental reform that were sweeping initiatives during this period, powerful institutional structures were created. These new institutions developed strict rules about how roads can be used and who had priority. Their mission was to take an asset of the public, city roads, and do what was necessary to facilitate travel by car. The efforts of this institutionalization sparked traffic signals, speed limits, and designated spaces for parking. All seem selfevident in hindsight. But in the early decades of last century, these innovations dramatically expanded how public space was regulated. The populous accepted these changes because motorized transport provided advantages that were previously, inconceivable.

Pursuing the aim of auto mobility for everyone invoked a cascade of effects, including but not limited to measures for their performance, ways to classify them, and standards to reinforce each. To this day, one of the auto industry's most celebrated victories came when, in 1924, the National Conference on Road and Highway Safety, convened by President Hoover, agreed to adopt the National Automobile Chamber of Commerce's preferred safety metric: fatalities per vehicle.

Strict classification systems emerged. In urban areas (at least in the US), roads were assigned to one of handful of categories: interstates, freeways and expressways, principal/minor arterials, primary/secondary collectors, and locals. What differentiated one category from the others had to do exclusively with how easy it would be, by automobile, to actually get to a destination. For example, principal arterials existed to move cars along the network and little else. Local roads, similarly responsible for moving cars through the network, also carried an additional burden. They actually allowed travelers to get within striking distance of a destination by facilitating turns and stops through curb cuts, driveways or allowing parking. The system created artificial inverse relationship between mobility function and access function of roads. Scant consideration was given to any other mode as this modern road hierarchy took form. Exclusive was concern to moving motorized traffic.

Two central criteria were enacted to measure how these roads functioned: volume and speed of motorized vehicles. Which roads were to carry how much traffic was an outgrowth of forecasts that were based on models in which it was assumed that an automobile was taken for every trip. Given that the auto needed a place to park at the end of the trip, minimum parking standards were installed in land use codes, thereby reinforcing the demand for other infrastructure requirements.

Given vehicular throughput was heralded as the central criteria for success, there was (and still is) little tolerance for any delay caused from traffic. Congestion jeopardized the free-flow of vehicles and such instances were viewed as weaknesses in the system. Given that the proverbial (infrastructure) tap was already open, more space was added to the network to satisfy the increase vehicular demand. The mobility system was deemed to be functioning well as long as cars are moving through the network of roads, preferably at fast speeds to minimize travel times. Even additional standards were introduced to ease free-flow speeds; these included regiments

prescribing the radii of curbs at intersections, the width of travel lanes, and aggressive signage. After all, public welfare was at issue and all roads needed to be able to easily accommodate quick response movement from a 35 foot long fire truck. With each mounting year, an unwavering mindset was reinforced. Additional legislation was added and even more minute standards were installed. Habits were formed and more roads with the same feel were stamped out by cities. Even older roads, those built in the first half of the 21st century, eventually became beholden to the standards aimed to make driving easier, such as through automatic road widening (Manville, 2016). This happened so slowly, the majority of the people didn't even notice.

Progressions

Such practices were not completely absent of critics. City intellectuals such as Lewis Mumford and Jane Jacobs, in the early 1960s, warned against continued proliferation of such auto centric ways. The plight of their claims, however, was largely steamrolled over, literally. Machines won in the end because transport and road building practices had already gained an overwhelming inertia. Cultural expectations that fundamentally allowed most roads to be hostage to a single mode were reinforced. Combined, these factors fueled a sense of path dependency that continues to this day. From these origins, cities have largely accepted that when they manage vehicular traffic they have been managing the right thing. The rise of auto mobility was so sudden, and so quietly supported by many public decisions (traffic engineering, parking requirements, paved roads, etc.) that decades of undisputed dominance for the motor vehicle has gained its own sense of inertia and path dependency.

The sirens forecasted by the likes of Mumford and Jacobs, however, did not completely fall on deaf ears. They warned that it was necessary to guard against the perils of everything cars and their thoughts helped sew a few seeds. Their thinking helped draw attention to how, by making travel easier for cars, it made travel by any other mode more difficult. They argued how by prioritizing mechanized travel, cities relegated human powered travel to a novelty act that eventually, would eventually have detrimental consequences. Bringing to light these arguments helped, at least, provide seeds that they sewed to grow slightly alternative thinking. When one thing is prioritized, another is diminished. This is a simple function of allocating scarce space.

Performance Measures

One focus of the assault targeted traffic engineers. Specifically, performance measures that guided their day-to-day work and Level of Service (LOS) standards were low hanging fruit. Not only did LOS measures aim to employ an objective formula to answer a subjective question—how much congestion people are willing to accept—these measures only gauged the success of roads through the perspective—or windshield—of car use (Dumbaugh et al., 2014). Some progressive engineers helped city leaders understand how a LOS score of C or D could strike a balance between over and underinvestment of the infrastructure needed. They, however, were in the minority. A few communities are slowly moving away from LOS guidelines, after decades arguing against their overall suitability, but what is replacing them is still far from perfect and still prioritizes vehicular travel.

One option specifies the success of a road by measuring how many vehicle miles it carries. A different alternative measures success based on the throughput of persons, regardless of the mode travel. Prioritizing the flow of people, by measuring person-trips (and not vehicular trips) is a step in a new direction. By definition, it represents a more humane goal because it accounts for the flow of individuals, regardless of their means of travel. And, by facilitating the flow of person trips regardless of mode, it has concomitantly helped support new road design approaches, such as complete roads (Hui et al., 2018) and processes of managing curb space as a scarce resource (King and Saldarriaga, 2018).

Following years of struggle, new guidelines are now available to design roads—guidelines which do not have the automobile at center of everything. Some progressive cities are adopting them. These guidelines have been undergoing underground transformative updates to better accommodate more diversity of transport modes and new design guidelines for the roads. For example, the American Association of State Highway and Transportation Officials (e.g., AASHTO and National Association of City Transportation Officials (Vega-Barachowitz, 2013)) for roads continue to offer tweaks that grant a stronger role to other human-scaled vehicles such as bicycles. However, these guidelines—progressive they might be—still subscribe to measuring throughput. They run up against an inherent limitation in they still principally gauge the success of a road based on how much activity is going through the corridor. They fall down in offering a sought ending place to value roads as anything *other* than a conduit for movement (Jacobs, 1993). Approaches to primarily legislate space in future roads based on particular types of modes are misguided; they fail to capture the essence of what many future roads in cities could or should be used for.

Owing in large part to the histories traced thus far in this chapter, changing the Overton window of what is possible to project new performance measure is difficult, to put it mildly. This difficulty is compounded because residents have a strong bias toward the status quo, even when the use of the status quo helps kill nearly 40,000 Americans each year. People also experience the city in perception and reality as motorists. Taking something away from drivers seems a personal attack for many.

Human-scaled Access

While throughput of anything will inevitably be one important element to consider for roads of the future cities, throughput by itself misses the mark. It fails to help understand other and more important dimensions. We contend that in deliberating future

performance criteria for roads, one fundamental characteristic stands out: how well are modes that support human-scaled access supported. The best way to do that is to moderate how fast things are moving, whatever that thing is. And, if the goal of preserving human-scaled access of roads through moderating speed can be overcome, other benefits will fall out.

The safety of movement on any road is predominantly affected by the size and speed by which things are moving. Both interact through laws of physics. Things that are moving faster gain more force and can do more damage than things moving more slowly. The size part of the equation comes in the form of cage to protect the user, usually of the metal armor variety, characteristic of cars, trucks, buses and the sort. Bigger and heavier objects, as opposed to lighter objects, compound the force, therefore increasing the differential in both the speed and size of transport users on the road. This is owed to the fact that if a collision happens, properties of kinetic energy take over.

The City of London rolled some of this logic out when Transport for London implemented new road guidelines. They described, for example, how a cyclist's fate is severely compromised when competing with vehicles that are faster or are superior in size and weight. Worse yet, both. A cyclist hit by a car hurtling at 40 miles/h results in a 70% chance that the cyclist will be killed. Should the cyclist be struck by a car moving 30 miles/h, there is an 80% chance they survive. A mere 10 miles/h can separate life from death.

Given the Cambrian explosion of vehicular types that are increasingly littering public rights-of-ways in cities, future roads will be well served to support varied transport modes. This raises fundamental questions around which decision makers need to come to grips. What defines a vehicle? Size, power, or shape? Some road users will inevitably be more vulnerable than others and it is a difficult problem to balance the needs of different types of users. The most vulnerable ones will be those lacking speed and size but that does not mean they don't belong. Moderating speed, regardless of mode provides a straightforward and robust target. Lowering speeds is the best, easiest, and fastest way to quickly radically improve the composition for roads, for both drivers and anyone in front of them.

Re-boot

A complete re-boot is needed to measure the success of roads such as locals, collectors, and likely, some arterials. Efforts to recalibrate an old needle will not cut it as they are, old. They fail to directly account for inevitable conflict among the increasing modal heterogeneity that will populate roads. They fail to capture the quality and experience of the movement. Safety and speed, working together, do.

Road planning processes from Northern Europe have been tending to such issues for decades. Localities from these contexts don't have all the answers, but they are further along than US counterparts in thinking through issues and identifying trouble spots. Take, for instance, Vision Zero, the road safety campaign that is sweeping the globe. Hailing from Sweden, Vision Zero aims for no deaths or serious injuries involving road traffic and use. It doesn't care what type of vehicle is at issue ([Johansson, 2009](#)). For US cities, where adopted, Vision Zero is perhaps the most compelling initiative to likely affect the actions of municipal transport departments and design of roads since that original 1924, performance measure was introduced.

In another example, in select corridors in some communities in Netherlands, long considered a leader in progressive road design, road planning efforts are no longer resorting to the traditional strategy of separating modes. Instead, they convert the whole road to all forms of movement based on a design speed. In so doing, they are removing barriers that help protect vulnerable road users, not adding them. In corridors with substantial bicycle traffic, other vehicles such as cars are permitted, but they do so on the terms delineated by the bike. Bringing multiple types of vehicles that are using road space into harmony with one another is the most important criteria defining successful streets.

A subtheme of roads that are built around the concept of speed, and not mode, is that it engenders a sense of social policing, where drivers are naturally cautious and people walking or biking feel safe. Standards for behavior are more firmly established and behavior that deviates from these standards adds a selfpolicing effect. The second effective strategy relies on enforcement, most often through technology. But focusing on enforcement can introduce new concerns about bias and profiteering in policing, which undermines political support but can also have devastating effects on individual freedom and liberty ([Seo, 2019](#)).

Based on the above rationale, we see a new breed of road emerging to fill a void in future transport planning. This new breed would be one that allows a road to be viewed both as a passageway and also as a form of connective tissue to socially unify residents. Both are advanced by using speed—as paramount considerations. This breed of roads falls outside the realms of traditional shopping roads, classic high roads or commercial corridors. It is also outside the bounds of most residential roads as they too separate play from movement. It is the type of road that is a neighborhood asset and amenity, supportive of a variety of users engaging in low-speed activities. It is premised on an ideology of using roads as public spaces for social interaction, commerce, play and also, movement.

There is risk in being over-prescriptive. Many cities installed pedestrianized roads in the 1960s and 70s which have never lived up to their promise (see Fulton Mall in Fresno, California as one example) ([Levinson and Krizek, 2018](#)). Other examples have worked. A one-size-fits-all recipe is too much to ask for. This admittedly makes it hard for planners and action-oriented officials. Trial and error is not a convincing policy platform and it certainly is not in the DNA of government. While private firms fail all the time (see recent bike share companies, for instance), it is important to safeguard against the public doing so. A city that tries and fails will be branded as wasteful, not enterprising. Futures that are inevitably different from the current are more difficult to plan for, especially under short time horizons (e.g., next year) and murky legal standing. While the legal legitimacy of road changes in beyond the scope of this chapter, any changes will have to be validated and upheld in court.

Concluding Thoughts

Motivated by the needs of planners and local officials to more quickly respond to a rapidly changing transport landscape, this chapter first helps understand why change is so hard. It provides context to allow readers to allow them of the formidable challenges facing those who shape roads—the performance measures, standards, and rules.

A troubling issue is that cultural and institutional practices regarding the nature of roads have become so sclerotic. Entrenched bureaucratic interests are geared toward preserving the status quo, thereby locking out society's ability to change them. Based on the evolving climate of micromobility, we argue that a new foundation is needed on which to build current-day and future policy. This provides future cities the opportunity to evolve to a more durable approach for future infrastructure that helps protect the public realm.

Innumerable obstacles to nonvehicular mobility exist in how roads are assessed, the standards guiding their design and the laws governing their use; each uphold car supremacy (Shill, 2019). This means that other social imperatives for cities such as the preservation of life, livability, and economic vitality fall to the wayside. One goal here was to identify the problem: sclerotic road planning. Leaders lack a way to intelligibly talk about this regime and knowing what needs to change is a first hurdle.

A second goal was to offer something that could or should replace it. Measuring performance by the relative speed and volume of cars is not only outdated, it is also counter-productive. Human-scaled accesses, regardless of mode, are two important characteristics for future roads to shoot for. The institutions that govern and manage roads are lacking criteria to reliably reinforce these metrics. This will inevitably involve new governance and policies that affect road use. Elected officials and the city planners that advise them deserve a more reliable north star to work towards. Managing speed helps provide such. Overcoming the automobile-centric nature of roads requires brutal realism—about what they could or should stand for and more pointedly, the sclerotic regulations, processes and mindsets that have guided their use. What can work for the future urban roads centers itself on what is important for cities to thrive: human-scaled access to services.

Introduction

Climate change, the health burden of pollution and economic cost of congestion are pushing policy makers to adopt measures to contain such externalities. Road traffic is widely considered as one of the main sources of externalities in urban areas, especially in developed countries, where manufacturing activities have re-located in the outskirts of cities. In 2013, congestion cost \$8.5 billion and 82 hours per driver in London. These figures are expected to rise by 63% in 2030 (Gordon and Pickard, 2014). Similar costs are faced by most of the world cities. According to Cohen et al. (2004), urban pollution causes up to 6.4 million premature deaths every year. Given this empirical evidence, policy makers are implementing measures at local level to decrease the concentration of some pollutants; in particular, through transport policy actions (OECD, 2010; Greater London Authority, 2006).

The aforementioned evidence is the empirical background for a vast series of measures designed to contain traffic and the use of private cars more specifically. Parking restrictions and pricing, expansion of the supply of public services, road pricing are all examples of traffic restrictions. To cope with the external costs of transport, several cities have introduced or are considering to introduce road pricing schemes, as in the case of: London (Banister, 2003), Milan (Percoco, 2013; 2014a; Rotaris et al., 2010), Hong Kong (Ison and Rye, 2005), Singapore (Santos, 2005), Stockholm (Eliasson et al., 2009), and several Norwegian cities (Ieromonachou et al., 2006).

In the case of London, pollution and congestion were considered to be the reasons that led to the then Mayor of London, Ken Livingstone, overseeing the implementation of the London Congestion Charge (henceforth denoted as LCC). The LCC, introduced in 2003 and then modified to extend the treated area, is probably the most known and studied example (Banister, 2003; Givoni, 2012; Ison and Rye, 2005; Prud'homme and Bocarejo, 2005; Quddus et al., 2007; Santos and Bhakar, 2006; Santos and Fraser, 2006; Santos and Shaffer, 2004). However, literature has not reached a consensus on the socio-economic convenience of such measures, since infrastructure and administrative costs seem to exceed the benefits in terms of a reduction in external costs (Mackie, 2005; Prud'homme and Bocarejo, 2005; Raux, 2005).

In this chapter, we will devote particular attention to road pricing schemes in terms of cordon pricing as a growing number of cities have introduced (or are planning to implement) such policy to curb externalities generated by urban traffic. Furthermore, we will devote special attention to the London Congestion Charge (henceforth, LCC), one of the most notable attempts to restrict traffic in a given area by using a pricing scheme. It should be noted that the effects of the LCC on atmospheric pollution is not clear a priori and it highly depends on the behavioral response of road users. On one hand, road pricing should reduce traffic volumes, given demand elasticity to changes in transport cost and this should result in an overall improvement in pollution concentration. On the other hand, the reduction in the number of cars reduces congestion, by increasing travel speed and this, in its turn, will result in an increase in fuel consumption and in a deterioration of air quality. Givoni (2012) has in fact argued in favor of a more robust statistical analysis of the effects of road pricing experiences. This is because figures used in ex post evaluations are, in general, unreliable and biased by other phenomena (confounding factors) not considered in the analysis.

The London Congestion Charge as a Prototype

London's fight against pollution has its origins in the second half of the XIX century; although it was only after the Great Smog of 1952 that the first policies were introduced, aiming to improve air quality. This event was disastrous for Londoners: a huge blanket of smog covered the entire city for four days and, by some estimates, caused the deaths of 4000 people (Mayor of London, 2002). Since then, air quality has much improved; although it remains one of the European cities with the highest levels of pollution. Road transport is a major cause of the high concentration of pollutants, accounting for about 40% of emissions of nitrogen oxides and more than 60% of particulates (Greater London Authority, 2006; Kelly et al., 2011).

In an attempt to reduce traffic flow, the LCC was introduced on February 17, 2003. The objective was to reduce congestion in the central area of London, covering an area of 22 sq. km, or 1.4% of the territory of Greater London. LCC consists of a daily payment to obtain permission to move freely in the area. The policy's enforcement is achieved through the use of cameras and the automatic recognition of cars' license plates. The charge is in operation from Monday to Friday, from 7:00 a.m. to 6:00 p.m. Initially, the scheme provided for a daily fee of £5. Subsequently, this increased to the current rate of £10. Exemptions are provided for the means of public utility, such as buses, vehicles of law enforcement, and for all vehicles powered by alternative sources of fuel. Finally, for the vehicles of the residents in the area, the price is discounted by 90%.

The stated objective of implementing the congestion charge was a 15% reduction in traffic in the central areas of London, with a simultaneous maintenance of traffic levels in the surrounding affected area. Transport for London (TfL, 2006) reports that in the first years of the scheme's operation, the number of cars entering the central area of London significantly decreased by 21%—with respect to the pre-treatment period, although with no significant changes in travel time. However, when considering the effect of the policy at the level of congestion, the results are less positive. In regards to congestion considered as excess delay, above conditions not congestion; in the first years of the policy's operation, there was a substantial reduction in the level of congestion in the order of 30%. However, since 2006; despite the previously mentioned reduction in the number of vehicles, the congestion level has increased, compared to the levels prior to the policy. The aim of the congestion charge was largely two-fold (TfL, 2004). First, to reduce congestion and second, to use the funds raised to improve transport infrastructure. In so far as private consumption of motor transport can be seen to impose negative externalities, for example, increased congestion, noise, pollution, etc., LCC can be thought of as a form of Pigouvian taxation. It can better equate the marginal private and social costs of transport; that is, to make individual agents incorporate external costs of their consumption into their private costs.

However, it should be noted that the marginal cost of congestion was not used as a basis for the charge. Instead, to find the optimal pricing scheme, simulations and models of household behavior were used to predict changes in traffic. Nonetheless, Santos and Shaffer (2004) state that the £5 per day charge is a reasonable approximation of the marginal congestion costs for an agent driving through the congestion charge zone.

How to Evaluate the Impact of Road Pricing on Pollution

The most promising empirical approach to evaluate the effects of road pricing is based on fairly recent literature using the Regression Discontinuity Design (henceforth denoted as RDD) to examine the impact of policies related to transport and air quality (Chen and Whalley, 2012; Davis, 2008; Percoco, 2013).

RDD is a non-experimental approach that uses ex post to evaluate a program's impact on a situation in which units are considered treated or not, according to a certain threshold in a reference variable (forcing variable). In our case, the date in which the traffic restriction was implemented is used as a threshold that introduces an exogenous variation in the access of polluting vehicles in the city. Thus, the expected outcome is a reduction in the level of pollutants. It should be stated that RDD identifies the impact of traffic restriction under mild assumptions; hence, it excludes the bias imposed by confounding factors.

Let y_0 and y_1 denote the counterfactual outcomes before and after the treatment T (the introduction of the policy), let x be the forcing variable (in our case, the time) and consider the following assumptions (Angrist and Pischke, 2009):

$$A1. E(y_g | T, x) = E(y_g | x), g = 0, 1$$

$$A2. E(y_g | x), g = 0, 1 \text{ is continuous at } x = x_0$$

$$A3. P(T = 1 | x) \equiv F(x) \text{ is discontinuous at } x = x_0, \text{ that is, the propensity score of the treatment has a discrete jump at } x = x_0.$$

Following Imbens and Lemieux (2008) the goal is to estimate the parameter ρ on treatment of this form (for the moment, we do not specify the model across locations):

$$y_{i,T} = \theta + \rho \text{Restriction}_i + f(\tilde{x}_{i,T}) + \eta_i \quad (1)$$

where $y_{i,T}$ in our case is the concentration of a given pollutant in day t whose treatment status is T (i.e., before or after the introduction of the restriction), θ is a constant, $\tilde{x}_{i,T}$ is the forcing variable properly normalized (a time trend centered at the date of the introduction of the policy, i.e., 17 February 2003). Consequently, ρ expresses the impact of the treatment at $x_{i,T} = x_0$. The $f(\tilde{x}_{i,T})$ term is a p -th order parametric polynomial to account for non linearity of the relationship between the time trend and pollution and thus to control that the eventual break in $x_{i,T} = x_0$ is not due to unaccounted non-linearity. Lastly η_i is an error term. *Restriction* is our treatment variable taking the value of 1 after the introduction of the congestion charge and zero before.

Seasonal and climatic factors are crucial in explaining the level of pollutants in the air. To deal with these problems in the reference model Eq. (1), seasonality is accounted for with day of the week, month and year dummies.

To make Eq. (1) operational for the analysis of the impact of the LCC and to account for the heterogeneity of monitoring stations, we have estimated an equation in the form:

$$y_{it} = \alpha_i + \rho LCC_t + \gamma LCC_t \cdot Treated_i + f(x_i) + \varepsilon_i \quad (2)$$

where α_i is a full set of station-specific fixed effects and $Treated_i$ takes the value of 1 if station i is located in the charged area and

NOX	74.82 (57.06)	88.11 (59.68)	76.30 (46.67)	99.03 (64.21)
SO ₂	7.033 (5.372)	9.670 (8.209)	4.553 (3.406)	7.211 (5.418)

zero otherwise. It should be stated that station-specific fixed effects are of particular relevance in Eq. (2) to identify the policy parameter γ as *Treated_i* is time-invariant. In all the specifications we make use of a 5th order trend polynomial and control for weather conditions and standard errors were clustered by month in order to account for possible spatial correlation. Seven days of temporal lags of the dependent variable are also used to account for the temporal persistence of pollutants, especially in the case of particulate matter. Finally, model Eq. (2) is estimated in logarithms, so that parameter estimates can be interpreted as percentage changes.

In Eq. (2), parameter γ identifies the effect of the policy in the charged area (the Average Treatment on the Treated), whereas ρ indicates the average effect of the introduction of the London Congestion Charge across stations, regardless of the their location.

The Impact of Road Pricing on Environmental Quality: The Case of London

To evaluate the case of London by using the empirical methodology described in the previous section, it is possible to use the data used in the analysis were made available by the LAQN (London Air Quality Network). They comprise daily observations of pollution from several monitoring stations in London, over period January–March 2003. The dataset contains information on the concentration of five pollutants: PM10, O₃, CO, NOX, SO₂. Of those pollutants, only SO₂ is less related to transportation. The concentrations of all the others are widely considered to be indicators of transport-related pollution (although not exclusively). Furthermore, information on: temperature, wind speed, rain, and humidity is also available^a. Table 1 shows a mean concentration before and after the introduction of the LCC. Interestingly, the results show a sizeable increase in the emission levels for almost all of the pollutants considered, also within the area where the congestion charge was implemented.

Results of the descriptive analysis in Table 1 are admittedly puzzling and need to be scrutinized in a more systematic way, through a parametric analysis. In Table 2, baseline models for the evaluation of the LCC are reported. They have been all estimated over the period January–March 2003 with a 5th order polynomial trend; weather controls and seven days of temporal lags of the dependent variable. In Panel A, we report results of the difference-in-discontinuity model in Eq. (2). A slight but only marginally significant increase in the concentration of PM10 is detected for the whole city and a significant reduction in the treated area is estimated in -0.059% . As for ozone, a reduction of an order of magnitude of 0.394% is found, with no significant spatial differentiation. Interestingly, as for CO, NOX, and SO₂ a significant increase in the concentration of pollution is detected, with a contemporary reduction in the treated area, although this decrease is significant only in the case of NOX. In Panel B, we consider only monitoring stations out of the treated area but located within 5 km from the boundary of the charged area. Therefore, the estimated model assumes $\gamma = 0$. Results confirm the overall reduction in the concentration of ozone, but also significant increases in PM10, CO, NOX, SO₂ with parameters ranging from 0.106% as in the case of PM10 to 0.513% for SO₂ (although, only marginally significant).

Finally, in Panel C, we have excluded monitoring stations located in the treated area and in the surrounding area within a 5 km arc distance. Therefore, we have considered only monitoring stations in the outer circle within a 10 km from the treated area. Also in this case results are confirmed: an overall decrease in O₃ equal to -0.277% and an increase in PM10, CO, NOX, and SO₂.

Overall, econometric results show unclear effects of the congestion charge in London. For some pollutants, such as PM10, CO, NOX, and SO₂, an increase in the concentration was found out of the treated area, with only small reductions in the charged area. This can be due to the diversion of traffic from the city center to external areas, with a subsequent increase in the kilometers traveled and the potential of polluting emissions.

^a It should be mentioned that the complete dataset covers the years 2000–2013. However, in this paper, we have restricted the sample to only three months (January–March 2003) to make our regression analysis comply with general practice of RDD consisting in restricting the interval around the threshold. An analysis over longer period was conducted with results qualitatively similar, although less reliable. Results are available upon request.

In particular, the Department for Transport makes traffic counts for the period 2000–13 available, with annual observations for 2141 count points. Count points have been geolocalized and hence assigned to three groups: *Treated* (if located in the congestion charge area), *Surrounding* (if located in a borough partially treated by the congestion charge or neighboring the charged area^b), or in the control group. In column 1 in **Table 3**, descriptive statistics of differences-in-mean is reported. In particular, statistics refer to the change in the mean of traffic counts before the treatment and after the introduction of the charge. It is noted that the pre-treatment mean is computed over the years 2000–02, whilst the post-treatment mean is calculated over the years 2003–05. Descriptive statistics show a decrease in the number of vehicles by 128,538 and 207,296 in the treated and controlled areas, although both estimates are not significantly different from zero. Interestingly, count points surrounding the treated area registered an average increase by 111,325 vehicles. This estimate is significant at a 99% statistical level. Together, these statistics imply a diversion of traffic from the treated to the surrounding area. However, a compelling parametric analysis is needed to account for unobserved heterogeneity and

^bThe following boroughs have been considered to be in the Surrounding group: Wandsworth, Lewisham, Greenwich, Newham, Waltham, Haringey, Barnet, Brent, Kensington, Hammersmith.

* $P < 0.1$.

time trend. To this end, the following difference-in-difference model can be estimated over the years 2000-2005:

$$traffic_{it} = \alpha_i + \beta trend_t + \gamma post_t + \delta_1 Treated_i \cdot LCC_t + \delta_2 Surround_i + ng_i \cdot LCC_t + \varepsilon_{it} \quad (3)$$

where the dependent variable is the number of traffic count in year t at count point i , α_i are count point specific fixed effects, $trend$ indicates a temporal trend, $post$ is a dummy variable taking the value of one after 2002 and zero otherwise, $Treated_i$ and $Surround_i$ are indicator variables for the treatment and surrounding group to which count point i belongs to. In model (2) in [Table 3](#) we consider $\delta_2 = 0$ and it emerges a decrease by 12,358 vehicles in the treated area with respect to the rest of the city, although this coefficient is not significant. In model (3) the full model is reported and it emerges that the introduction of the congestion charge has resulted in an increase in traffic counts by 279,596 vehicles. This figure is statistically significant, whereas no significant (at conventional level) change is found in the treated area.

Estimates in [Table 3](#) corroborate the hypothesis advanced previously to justify the finding of a decrease in pollution concentration in the treated area and an increase outside of this area. However, results may still hide some heterogeneity in terms of traffic composition. In [Table 4](#), the sample is split into four categories (heavy goods vehicles, light goods vehicles, cars, motorbikes) and the number of bikes is added. Interestingly, the introduction of the LCC has decreased the number of heavy goods vehicles by 13,434 units in the treated area, although this estimate is only marginally significant. Additionally, no significant effect is found in the case of light goods vans; whilst, in model 3, a clear increase in the surrounding area by 242,411 cars is estimated. According to estimates in models 4 and 5, an increase by 34,664 and 30,335 occurred in the case of motorbikes and bikes. Hence, from an environmental perspective, a shift towards uncharged vehicles (and in this case, motorbikes) is not efficient. Another possible transmission channel might make a change in the kilometers traveled; drivers may be willing to avoid the charged area by traveling longer routes around the area. Finally, it should be noted that these simple results are vastly consistent with the results obtained in the case of Milan ([Percoco, 2013](#)).

Conclusion

In this chapter, the environmental effects of road pricing schemes have been discussed with specific reference to the London case. The exogenous variation in traffic flows after the introduction of the policies was used to estimate a variation into the concentration of: PM10, O3, CO, NOX, SO₂. A negligible effect of the policy was found, along with a spatial displacement effect, since a reduction in the concentration of several pollutants in the treated area and an increase in the surrounding areas was found. In particular, a significant decrease in the concentration of O3 was found across the whole city of an order of magnitude of -0.4% (on average). CO, NOX, and SO₂ present significant increases by 0.4%–0.5% (on average) in the area surrounding the charged area. A reduction in the concentration of PM10 and NOX was also found in the charged area. Overall, in terms of pollution concentration of the whole city, it seems that congestion charges have limited or even adverse impact, possibly because of the spatial diversion of traffic. This result calls for careful consideration of the spatial extent and of the cross elasticity of traffic flows when implementing road pricing schemes.

An important factor for the interpretation of the results is the relationship between emissions of a given pollutant and average speed. In fact, the relationship between the production of nitrogen oxides and traveling speed is directly proportional to the vehicles with diesel engine ([EEA, 2010](#)). Thus, an increase of the vehicle's average speed is due to a greater production of nitrogen oxides. This might be relevant because of the reduction of congestion caused by the introduction of the charge, especially in the early years after the policy was introduced ([Greater London Authority, 2006](#)). However, the relationship between pollutants and average speed of vehicles is still not very clear, especially for ozone and particulates, and further studies are needed to shed light on this issue ([EEA, 2010](#)).

Introduction

The general consensus is that car use needs to be reduced given its serious negative impacts on the environment (Garling and Steg, 2007) and on human well-being, including the growing health problems caused by car-related sedentary lifestyles (Dora and Phillips, 2000). Despite these negative effects, why do many people continue to own and drive a car?

This article gives an overview of psychological factors that are related to car ownership and car use. The relationship between car use and car ownership is a matter of debate and the view on this relationship differs between research disciplines. In psychology car use is often studied in context of the broader topic of traveling behavior. Psychological studies mostly use general concepts from psychological theory, and apply them to traveling behavior in general or car use more specifically. Car ownership is, however, hardly studied. In this article, we will therefore discuss psychological factors that influence travel behavior with a focus on private car use. The premise being that people who use a private car are mostly car owners. Although, in recent years other forms of car use without car ownership are becoming more popular the market share of car-sharing is still small as compared to car-ownership (Loose et al., 2006), indicating that car users are probably mostly car owners.

We will start this article by discussing motives for owning a private car and the influence of the social context on private car use. We zoom in to how personal values, beliefs, and norms are related to car use and discuss the influence of past personal experiences with other modes of transport on car use and the difficulty of changing car use habits. Next, we discuss how knowledge on psychological factors influencing car ownership and use can be used to design interventions to reduce car use, for example by promoting car sharing. Last, we will discuss the influence of pricing policies on car use.

Motives for Car Ownership and Car Use

Generally, when people are asked why they own a car, they will come up with all kinds of practical arguments, such as my car gives me flexibility to go to work at any time; the car enables me to bring my kids to school. This illustrates that car ownership is generally regarded as mostly utilitarian and practical. However, besides the convenience a car brings it is also a means to express one's identity. For example, individuals can express that they have high status by owning an expensive car, or show that they care for the environment by driving an electric vehicle, meaning that besides the often first-mentioned instrumental motives for owning a car, there are also symbolic motives that influence car ownership. Also, for many people driving is in itself a positive and enjoyable activity (Gatersleben, 2007; Mokhtarian, 2005; Steg et al., 2001; Steg, 2005). In other words, people have several motivations for owning a car. Steg (2005) studied motivations of private car use and in line with Dittmar (1992), proposed that the motivations to use the private car fall into three categories: Instrumental, Symbolic, and Affective motivations.

Instrumental motives are defined as practical motives such as the convenience or inconvenience a car brings its owner (Crossreference: 10677: Car use benefits). Symbolic motives reflect the extent to which one can express one's identity and enhance one's status by driving a certain car. Affective motives refer to various emotions that can be evoked by driving a car, such as pleasure, excitement, or relaxation but also stress or anxiety. In line with this, Steg and Tertoolen (1999) proposed a theoretical model in which they illustrated how these motivations influence each other and private car use (see Fig. 1). As shown, the instrumental and

[#]Veldstra and A.B. Ünal contributed equally and have shared first authorship of the paper.

Figure 1 Motivational model for private car use. Source: [Steg and Tertoolen \(1999\)](#).

Figure 2 Value-belief-norm theory. Source: Adapted from [Stern \(2000\)](#).

symbolic motives influence the affective motives meaning that if one regard driving a car as convenient, low cost, and safe, for example, and one also feels one can express who they are with the car, they are likely to appraise driving it as giving them a good feeling, which in turn makes using the car more likely.

[Lois and López-Saez \(2009\)](#) tested this model empirically to predict the frequency of car use from the motives for car use and found that the affective link one has with one's private car explains 12% of the frequency of car use. They also found that the symbolic and instrumental appraisals predict this affective link, confirming the hypothetical relationship between affective, instrumental, and symbolic motives as proposed by [Steg and Tertoolen \(1999\)](#). These findings also indicate why it is difficult to convince people to switch to other transport modes with similar instrumental qualities. People are less willing to give up on driving because they seem to enjoy it and they seem to associate it with prestige and high-status. Can we then also make environmentally friendly alternatives attractive to people?

In a recent study, researchers replicated the study of [Steg \(2005\)](#) by applying it to the purchase of electric vehicles ([Noppers et al., 2014](#)). The findings revealed a similar pattern. Participants indicated that instrumental aspects of electric vehicles were more important to them in their decision to buy an electric vehicle, but purchasing intentions were actually better predicted by the evaluation of the symbolic and environmental aspects of the electric vehicle. More specifically, the intention to purchase an electric vehicle was mostly associated with gaining status. This finding is in line with [Egbue and Long \(2012\)](#), who proposed that early adoption of innovations is associated with high-status amongst people. Hence, people might prefer certain transport modes, including relatively environmentally friendly modes, if they are associated with high-status and prestige ([Noppers et al., 2014](#)). In other words, mobility choices might have a signaling function that is used to convey one's identity and status.

Given the rise in new technologies, trends, and innovations in the domain of mobility (such as automated vehicles or transport apps), the potential signaling function of the adoption of green mobility innovations seems to be very relevant to promote sustainable options.

Personal Values, Beliefs, and Norms

Sustainable modes of transport do not always score high on the three main motivations to use and own a car that we discussed above. For instance, using a bike would score low on instrumental aspects because it takes longer to travel from A to B with a bike as compared to a car. Similarly, when it is cold or rainy, riding the bike would be rather inconvenient and costly for the individual as compared to the comfort of private car. But does this mean that efforts to reduce car ownership and car use are doomed to fail? As we will discuss below, moral considerations could play a role in achieving a sustainable mobility transition despite the seeming disadvantages such as inconvenience. So the question is to what extent moral considerations play a role to change to sustainable mobility behavior and what kind of process would fuel the activation of moral norms among car users?

According to the Value-Belief-Norm (VBN) theory ([Stern et al., 1999](#); [Stern, 2000](#)), a value-triggered norm-activation process predicts moral actions, such as prosocial and proenvironmental behaviors. Notably, the VBN theory proposes a causal chain of relationships (see [Fig. 2](#)) whereby personal norms that are defined as one's feeling of moral obligation to act in a particular way ([Schwartz, 1977](#)) are the direct predictors of behavior. For example, when people have strong personal norms to reduce car use, they are more likely to accept car use reduction policies ([De Groot et al., 2008](#); [Jakovcovic and Steg, 2013](#); [Ünal et al., 2018](#)).

Such activation of personal norms, in turn, depends on whether one is actually aware of the problems resulting from car use, such as increased air pollution or reduced space for other road users like pedestrians (i.e., problem awareness) and whether one

recognizes that she/he contributes to these problems by using the car (i.e., ascription of responsibility). According to the VBN theory, when one feels such responsibility, one is also more likely to feel a personal moral obligation to change behavior.

The VBN theory further posits that problem awareness is triggered by values, which are defined as goals that transcend time and situations and that act as guiding principles for people (Schwartz, 1992). Four values seem to be of particular relevance when it comes to proenvironmental behaviors like car use reduction: biospheric, altruistic, egoistic, and hedonic values (Steg et al., 2014; De Groot and Steg, 2008; Stern, 2000; Stern and Dietz, 1994), which we will elaborate below.

People who endorse biospheric values have a strong concern to reduce their environmental impact and to protect the environment and natural resources. People with strong biospheric values would therefore act proenvironmentally even though it is somewhat difficult or costly to do so. They would, for example, not mind giving up their car despite some inconvenience it would bring if this behavior would benefit the environment. People who strongly endorse altruistic values have a strong concern to help improve the well-being of others in general. They would act pro-environmentally when it is good for the community and the well-being of others. They would for example give up owning a car to help others, maybe to create green space for social activities instead of holding it for parking cars. Since biospheric and altruistic values are both not directed at gains for the self but rather put emphasis on goals that are beyond the self, they are called selftranscendence values (Schwartz, 1992).

Egoistic and hedonic values, on the other hand are called selfenhancement values since they do put emphasis on personal gains and pleasure (Schwartz, 1992). The difference in these two value types lies in the type of benefits sought. People who endorse egoistic values have a strong concern to improve benefits, including financial benefits or status. As such, people with strong egoistic values will act proenvironmentally particularly when it brings those financial gains or when it is status-enhancing to do so. People who strongly endorse hedonic values have a key concern to maximize pleasure and fun. This means that people with strong hedonic values will act proenvironmentally particularly when it is pleasurable right now. Reducing car use is oftentimes perceived to be not very pleasurable meaning that it might be difficult to move toward sustainable behavior, especially for people with strong hedonic values.

Research largely supports this reasoning. Strong biospheric and/or altruistic values are found to trigger a process of norm activation by having a positive impact on problem awareness (De Groot and Steg, 2008; De Groot et al., 2012; Jakovcevic and Steg, 2013; Nordlund and Garvill, 2003; Steg et al., 2005; Stern, 2000; Ünal et al., 2018; Ünal et al., 2019), which in turn was found to be related to recognizing one's own contribution to these problems (ascription of responsibility) and feeling a moral obligation to act sustainably (personal norm). On the other hand, strong hedonic and egoistic values were found to be either not related to problem awareness or negatively related (De Groot and Steg, 2008; De Groot et al., 2007; Jakovcevic and Steg, 2013; Stern, 2000; Stern et al., 1995; Thøgersen and Ölander, 2002; Ünal et al., 2018; Ünal et al., 2019). These findings indicate that values could act as a motivational source to trigger sustainable mobility decisions and behaviors. Yet, sometimes, even people with strong biospheric values might find it hard to drive less. For instance, when it is pouring rain and one need to bring children to school and everyone around you is driving to school with their private car, even those with strong biospheric values may decide to drive to school as well. In the following sections, we will elaborate on these other psychological factors that might have an influence on our decisions and sustainable behaviors.

Social Norms

Determining one's mobility behavior and decisions are not only influenced by individual characteristics, such as values, beliefs, and personal norms, but also by the perception of what others do (descriptive social norms) or what we think that others expect us to do (injunctive social norms) (Cialdini et al., 1990). For instance, if a person thinks that the majority of the people in their neighborhood use public transport instead of owning a car, then using the bus becomes a descriptive norm in that environment. Descriptive norm can influence individual actions as they reflect what is the appropriate and sensible thing to do, and we tend to think that the majority will make the most sensible choice. That is, if the majority is doing a particular behavior, that must be the right behavior.

Communicating the descriptive norm can be effective in influencing one's behavior by for instance, emphasizing the extent to which others engage in the desired behavior in information campaigns, and providing information to people about what others do when it comes to this particular behavior. For example, if a municipality of a city wants to motivate car owners to commute by bike instead of by private car, they could inform their citizens that the majority of people living in their city travel to work by bike. However, in some instances the undesired behavior can be the descriptive norm. For instance, at the moment, driving is still a strong descriptive norm, as the majority prefers to drive a vehicle, which might make other people to adopt a private vehicle or ignore car use reduction campaigns. As such, descriptive norm can influence behavior in both directions: it not only reinforces the desired behavior but also the undesired behavior. In that respect, information regarding the descriptive norm should be credible to be effective.

Injunctive norms, on the other hand reflect unwritten rules about what a person thinks others expect him or her to do in a given situation (Cialdini et al., 1990). People follow injunctive norms to gain social approval, or avoid social disapproval. Different than descriptive norms, injunctive norms do not only tell what is the right thing to do at a certain moment, but they also signal that norm-violations would be associated with social sanctions while normative behavior would be associated with social rewards. Hence, when an injunctive norm is violated, this could have social consequences for the individual, such as being negatively judged by one's immediate community. As such, communicating the injunctive norms can also be used to change behavior. But what happens when there is a mismatch between descriptive and injunctive norms? How would an individual behave when the rule is not to drive your

kids to school and no cars are allowed in front of the school but almost everyone is driving their kids to school and parking in front of the school?

In such situations where there is a conflict between the injunctive and descriptive norm, the most salient norm becomes most influential (Reno and Kallgren, 1990). Following from the above example, an injunctive norm, such as a no-parking sign in front of the school, might make it more salient that other drivers are not obeying the rules (descriptive norm), increasing the likelihood that one follows the descriptive norm of disregarding the no parking sign. Situational cues (e.g., signs) are crucial in that respect in underlining whether other people are following the norm or not; thereby increasing the chances of norm-abiding or norm-violating behavior. [Sparkman and Walton \(2017\)](#) argues that particularly for behaviors like car use indeed, which are clearly carried out by the majority, the descriptive norm as a static and seemingly unchanging norm might work against sustainability.

They reason that for such behaviors it would be more effective to inform people about the so-called dynamic norm, which would emphasize that there is a change in the behavior of some large group of minorities. Following their reasoning, it would be an effective strategy to tell that “30% of the people last year reduced their car use and switched to other modes of transport” because such information would make it salient that there is a trend of car use reduction in the society, which would increase even further in the future. Indeed, anticipation of future behavior (referred to as pre conformity by the authors) seems to explain how dynamic norms could affect behavioral intentions as well as real behavior in the desired direction. When the idea of “changing norms” is salient in people’s minds, they seem to be more open to considering changing individual behavior.

The Influence of Past Personal Experiences and Habits

[Weinberger and Goetzke \(2011\)](#) proposed that the choice to use the private car is influenced by what people have learned from past experiences. They propose that when people have no experience in using public transport, for example, it may not be part of their choice pallet when making travel decisions. Hence when faced with travel decisions, people might choose to drive a private car even if that may not be the best choice given the circumstances. [Weinberger and Goetzke \(2011\)](#) illustrate this by comparing two hypothetical women with the same demographic characteristics moving to a transit-rich city. One woman moving from a rural area where one needs a car to get out and about and one woman from another big city who has experience using the tube, bus and even shared cars. They propose that the first woman, having no experience with public transport, will be more likely to continue using a car since she is used to driving to get around. She may either not even think of using the tube instead of the car, or the fact that she does not know how the system works may be an obstacle for considering it as a viable option since she has to invest time and energy into learning it, and thus the high nonmonetary cost. In addition, she might have some misperceptions regarding public transport due to lack of experience with it, such as public transport being crowded all the time or tickets being expensive. For the second woman the differences in public transport systems of two cities is a small challenge that will not stop her from using it as she has experience with public transport and it is a natural part of her choice pallet. She will continue to decide on what mode serves her best given the trip.

This is in line with the proposition that mobility behavior is often habitual (Crossreference to 10656: Habitual behavior) ([Verplanken et al., 2008](#)), meaning that once you are used to behaving in a certain way, or in this case choose a particular form of transport, you will most likely keep doing that as long as the consequences are satisfactory. As a result promoting car use reduction and promoting the use of more sustainable ways of transport instead might be difficult because people might find it easier to follow what comes habitual to them.

Habits are indeed a barrier to safe and sustainable transport ([Verplanken et al., 1997](#); [Verplanken and Wood, 2006](#)). More specifically, people with a strong habit of car use were found to seek less information regarding alternative ways of transport, and they required less travel-related information (such as on whether conditions) to decide whether they would pick a car or not ([Verplanken et al., 1997](#), also see [Aarts et al., 1998](#)). These findings suggest that habit strength leads to a biased way of thinking and information seeking, or even a shallow way of processing new information regarding alternative modes of transport. As a consequence, the habitual behavior of car use is likely to remain unchanged.

It appears that people reconsider habitual behaviors only when they experience drastic or natural changes in their lives. For instance, there has been evidence suggesting that habits can be countered, especially for those individuals who are in a transition in their lives, such as moving to a new neighborhood or changing offices ([Fujii and Garling, 2003](#); [Verplanken and Wood, 2006](#); [Walker et al., 2014](#)). Such natural changes in one’s life seem to provide a good opportunity to inform people about alternative ways of commuting, and getting them try out more sustainable modes of transport. Enriching their perceived choice pallet is therefore best tried when circumstances change because habits are strongest in the context that they had been initially developed: the context serves as a cue, eliciting the automated behavior ([Verplanken and Wood, 2006](#)). When such contextual cues are not present in the environment (which is provided in the example of moving to a new neighborhood), then habit strength is weakened, leaving room for considering alternatives and behavior change toward the desired direction.

In addition, a new context might also make people think about possible ways of commuting in that neighborhood in a more systematic way, which might make people, reconsider the automatic behavior of driving. It should be noted that even in new circumstances where habit strength is weakened, it might still be very difficult for people to cease car use, particularly if people do not have much experience with other transport modes ([Weinberger and Goetzke, 2011](#)) but also if alternative modes of transport are unavailable or somewhat difficult to use. Hence, interventions to break habits could best be supported by making the alternatives

available and attractive to people. When the alternative behavior is (cognitively) costly and effortful, it might indeed inhibit us from following it, which we will elaborate on in the next section.

Perceived Costs

Earlier we discussed that moral considerations (i.e., personal norms) have a strong motivational power to stimulate proenvironmental behavior such as reducing car use. But do moral considerations predict any behavior or are there some preconditions for moral considerations to be most effective? We will elaborate on this question in the light of two competing theories that both focus on perceived cost of executing a behavior as a key determinant: the low-cost hypothesis (Diekmann and Preisendörfer, 2003) and the A-B-C Model (Guagnano et al., 1995).

According to the low-cost hypothesis (Diekmann and Preisendörfer, 2003), motivational factors such as attitudes or personal norms would predict behavior only if the behavior is a low-cost behavior, meaning it is not an effortful or largely inconvenient behavior. That is because when the costs are too high, it is assumed that no one will execute the behavior irrespective of the level of their motivation. Hence, the low-cost hypothesis assumes an interaction between perceived cost and motivational factors in which behavior is predicted by motivational factors such as moral considerations when perceived costs are lower. Evidence for the low-cost hypothesis comes from studies that found that moral considerations were strong predictors of intention but not actual behavior (Abrahamse et al., 2009). Similarly, it was found that personal norms were more predictive of car use reduction for short-distance trips, which can be considered rather feasible than for long distance trips (Keizer, 2014). Leaving the comfort of one's private vehicle to travel by public transport, when distances are somewhat bigger would probably be regarded as rather costly and very unattractive (Anable and Gatersleben, 2005).

The A-B-C model (Guagnano et al., 1995) gives support to the low-cost hypothesis that moral considerations would indeed not be related to executing behavior when costs are very high. In a similar way, the A-B-C model posits that when costs are too high, motivation would not be sufficient to carry out behavior. Interestingly and as opposing to the low-cost hypothesis, the A-B-C model further argues that moral considerations would not be related to behavior when costs are too low either. Notably, the model predicts that moral considerations would affect behavior only when perceived costs are moderate, thereby pointing out to a curvilinear relationship between perceived costs and motivational factors in affecting behavior. In other words, when behavior is somewhat costly but still doable, then motivational factors come at play to trigger the right behavior, which is depictive of a U-shaped relationship between motivational factors and perceived costs.

A recent comparison of the low-cost hypothesis and the A-B-C model in explaining policy acceptance for car use reduction measures revealed that moral considerations were not related to the acceptance of a low-cost policy measure that will have no negative impact on one's driving (i.e. improvements in public transport), supporting the A-B-C model, and opposing the low-cost hypothesis (M. Keizer et al., 2019). In addition, moral considerations were found to be related to the acceptance of a high-cost policy measure on car use reduction (i.e., paying tax for car use), when people felt more able to reduce their car use, indicating a somewhat moderate perceived cost, supporting the A-B-C model.

In short, perceived barriers and costs to reduce car use or stop car-ownership might inhibit sustainable mobility behaviors. An important step to stimulate or sometimes even mandate the right behavior is to develop transport policies that are effective. But what kinds of transport policies are most effective to reduce car use or ownership? And to what extent are they acceptable?

Transport Policies

Policies aimed to encourage car use reduction can be broadly defined as pull and push policy measures (Steg and Vlek, 1997). Push policy measures are those that aim at changing behavior by "forcing" the individual to behave in a certain way. Examples are implementing transport pricing measures, congestion taxes or charges, or reducing parking spaces. Pull policy measures aim at changing behavior by making the desired alternative more attractive. Campaigns on raising awareness on public transport, offering daily commuters a free travel card for a couple of weeks or changing infrastructure to include e-bike charging stations are examples of pull policy measures.

Pricing strategies, which are commonly implemented by policy-makers often aim at reducing the financial costs of using environmentally-friendly means of transport (e.g., pull measures) or increasing the financial costs of environmentally-harmful modes (e.g., push measures; Thøgersen, 2009; Schuitema and Steg, 2008). In one particular study, Danish car-owners were given a voucher that allowed them to travel with public-transport for a full month for free (Thøgersen, 2009). The idea was to break their car use habit, and to help them develop positive associations regarding the use of public transport, such as regarding the quality of service and the convenience of using public transport. Findings revealed a positive effect of the intervention on the frequency of using public transport. Notably, the price promotion led to an increase in the use of public transport, which was twice as much than the use of public transport before the intervention. The positive influence of the price promotion lingered for a period of 5 months after the removal of the price promotion. This suggests that promoting the use of public transport by making it financially appealing to car-owners might lead to a long-term change in transport behavior, even after the financial incentive is removed (Thøgersen, 2009). Importantly, a positive experience with public transport might help change the misperceptions about the quality of public transport

(Fujii et al., 2001), and a financial incentive might be useful to make people be open to such an experience at the first place (Fujii and Kitamura, 2003).

Similar findings have been reported when it comes to the acceptability of pricing policies in the form of a congestion charge, meaning a tax that needs to be paid when you enter or leave the city center (Nilsson et al., 2016; Schuitema et al., 2010). For instance, before the introduction of a congestion charge in Stockholm, acceptability of this pricing policy was low because people expected an increase in financial costs and a restriction on one's car use. Interestingly, acceptability increased after the implementation of the congestion charge. Findings suggest that acceptability was probably higher because the charge had more positive effects than people anticipated, such as reduction of environmental and parking problems. Furthermore, the pricing policy was supplemented with infrastructural improvements such as an increase in the frequency of public transport service in Stockholm, which could have made it easier for car users to reduce their car trips and consider other more sustainable transport modes.

Yet, incentives do not always work as intended, and might only be effective in the short-term. For example, in one study, drivers were given a discount on their insurance premium if they adopted an environmentally friendly and safe driving style by driving according to the speed limit (Bolderdijk et al., 2011). Their driving behavior was observed via GPS devices. It was found that drivers indeed reduced their speed when incentivized, and engaged in less speeding violations as compared to another group of drivers who were not given a discount on their insurance. Interestingly though, when the financial incentive was removed, drivers increased their speeding violations again, and eventually, the difference between those who received a financial incentive, and those who were not given the financial incentive vanished. This finding indicates that it might be very difficult to have long-term behavioral changes with short-lasting financial incentives, especially when the targeted behavior has no positive individual rewards in the long-run.

Summary and Conclusions

In this article, we aimed to give an overview of psychological factors that influence car ownership and car use. In view of the general consensus that car use needs to be reduced in the face of negative impacts on the human environment, behaviors such as less car use or buying an electric vehicle instead of a fossil-fuelled car can be promoted. Achieving a sustainable mobility transition depends for a large part on the extent to which people are willing and feel that they are able to change to sustainable mobility behavior though. As we discussed, feelings of moral obligation to use a sustainable mode, awareness regarding problems resulting from car use, and a sense of personal responsibility seem to predict sustainable mobility intentions and behaviors. Notably, this process of norm activation can be triggered by personal values, and particularly biospheric values.

Mobility behavior is not only influenced by individual characteristics but also by the perception of what others do, what individuals think others expect them to do as well as what behavior is becoming more common in the society. Such knowledge of these social norm mechanisms can help to change behavior by for instance, reminding people of the trending sustainable mobility behaviors that other people are doing.

Habitual behavior and past experiences, such as a strong car use habit, might challenge the transition to sustainable mobility behaviors. That is because changing habits can be cognitively effortful and require the processing of new information, meaning that behavior change is usually perceived as very costly and effortful for people with strong car use habits. As discussed, it is still possible to challenge perceived barriers and costs to promote sustainable mobility behaviors. For instance, people with a car use habit could be approached in moments when they are going through a transition in their lives, such as moving to a new city, as research shows that they will be more open to new information in such times.

To summarize, several psychological factors including individual, motivational, perceptual, and habitual factors could play a role in affecting people's car-ownership and cars-use behavior. By designing evidence-based interventions that stem from psychological theories, we can stimulate car use reduction and sustainable mobility behaviors.

Introduction

Micromobility has become a catch-all term for several modes of transportation and is becoming popular for its convenience and environmental friendliness. It will play a huge role in the transition toward Smart Cities. The term includes fully or partially human-powered of small and lightweight electric-driven vehicles, for example, bicycles, e-bikes, e-scooters, human pods, e-skateboard, and other single-person vehicles as shown in the figures. In this concept, the main idea is that all people should have the right to get access to more affordable modes of transportation. Shared mobility has emerged to be one of the cheapest and fastest ways of moving from point A to point B. These systems are an increasingly important part of city transit and mobility systems, as they help people move around cities more seamlessly and efficiently (Fig. 1A–D).

Recent years, since 2018 in particular in the United States and since 2019 in Germany, have been marked by a race toward micromobility, where bikes and e-scooters provide a new way for residents to move throughout their communities. While there is a great deal of promise with these innovations, the emergence of micromobility comes with its own set of challenges and considerations for planners, residents, and local decision makers. At the same time, many communities still have vast surface transportation needs, which must be addressed for micromobility to take shape.

E-scooters are an urban trend in transportation as a way to get around. This class of mobility has truly taken off. From the different categories of electric vehicles, e-scooters were found to be the most disruptive due to their ride-share growth. E-scooters are convenient, cheap and comprise first and last mile options. They have been deployed by start-up companies quite often without any communication between cities and the start-ups. Because of not communicating a plan regarding regulations with the local government, many scooter programs failed or were rolled back due to temporary bans.

To grasp a better understanding about e-scooters, key facts are shown in section, Background and Context and the benefits of the use of e-scooters are described in section, Benefits. Section, Challenges and Opportunities displays challenges and opportunities for these modes of urban mobility transportation. To conclude, section, Anticipated Future Impact describes the anticipated future impact, while section, Conclusions and Recommendations summarizes a set of recommendations that cities can consider as they work to regulate the use of e-scooters.

Background and Context

Since the first scooter sharing system was launched in Santa Monica, California in 2017, the e-scooter market is growing day after day. Numerous e-scooter operators have received vast amounts of venture capital funding and rapidly spread to cities worldwide.

The global electric scooters market size was estimated at USD 18.6 billion in 2019. Only the US micromobility market is expected in 2030 to be worth between 200 and 300 billion US dollars. In Europe alone the market for shared e-scooter services is expected to reach at least 12 billion US dollars by 2025. There are more than 150.000 scooters in cities in the United States and Europe available for sharing (Mobility Foresights Transportation, 2020).

In September 2019, there were more than 10.000 units of e-scooters in Berlin, Germany and 2.865 units of e-scooters in Portland, United States (from April 26 to November 30 of 2019, rental e-scooters in Portland traversed 1.01 million miles during 954,000 trips). As of March 2020, e-scooter sharing services are available in 177 US cities and European cities, down from 223 cities in December 2019. In addition, in March 2020, cities such as Paris, Madrid, and Berlin were ranking as the three main European cities in terms of the size and use of fleet of e-scooter sharing (Mobility Foresights Transportation, 2020).

How can one explain the varying performance of the major scooter providers across different cities?

Figure 1 (A) Different vehicles currently implemented in the micromobility market: electric bikes. (B) Different vehicles currently implemented in the micromobility market: electric scooters. (C) Different vehicles currently implemented in the micromobility market: human pods. (D) Different vehicles currently implemented in the micromobility market: electric skateboards.

The year 2018 was the decline of many ride-hailing and bike-sharing operators. Many new start-ups foraying the e-scooter sharing market gain more strength in the urban mobility. According to the National Association of City Transportation Officials—NACTO's Guidelines for Regulating Shared Micromobility (2019), the addition of e-scooters boosted the total number of micromobility trips from 35 million in 2017 to 84 million in 2018. In fact, e-scooter operators have already pumped in \$5.7 billion into the industry and looking to capture new cities and urban spaces around the world.

The number of companies is still growing in several cities on several continents and has positive and negative impacts on the society. Lime and Bird, for example, two of the largest companies, are currently valued at \$ 1 billion and \$ 2 billion, respectively. **Table 1** shows the profile of some major e-scooter operators.

There are several models for how these systems are managed. In the United States, the competitive landscape is extremely consolidated. In Europe, on the other hand, it is comparatively fragmented with local players like Tier in Germany that is giving a tough fight to the American duo—Lime and Bird. The fleet of e-scooter vehicles might be owned and maintained privately, like the e-scooter provider VOI and Lime, or owned and maintained publicly, like Tier in Germany, which uses a hybrid model which is publicly owned but privately maintained.

E-scooters (sharing) are now located in all major US and European cities except London where it is prohibited (some cities have banned scooters or are taking plenty of time to think about appropriate introduction and rollout). The Asian market of e-scooter sharing industry is currently less than 4% of the US market size. They are not only available for rental in major cities but also in medium-sized cities with around 200,000 inhabitants or less.

Regulations and fleet size vary from country to country, even from city to city, an ever-growing number of companies is placing as many devices as they can in as many cities as possible. Many cities don't have a balance of size and fleet distribution (Madrid in Spain alone has authorized 18 different operators) in an attempt to achieve market dominance. Due to higher upfront licensing costs per e-scooter and reduction in the max fleet size allowed per operator in many cities, some e-scooter operators have started scaling down their fleet size. According to Mobility Foresights Transportation (2020), Lime, the global market leader in e-scooter sharing, has significantly scaled down its US presence, that is, around from 90 cities in December 2019, to 54 cities in March 2020.

To understand more about e-scooters, the following paragraph describes the benefits, challenges and opportunities for the sector.

Table 1 E-scooter operator's profile

Operator	Profile
LIME	Founded in 2017, LIME is an electric scooter startup base in San Francisco raised over \$455 million of capital. Lime has a fleet of 120,000 e-scooters.
BIRD	Founded in 2017, Bird is a micromobility company based in Santa Monica-California is a dockless scooter sharing startup. Bird raised over \$455 million of capital. Operated shared e-scooters in over 100 cities in Europe, the Middle East, and North America.
GRIN and YELLOW	Founded in 2018, is a Brazilian startup and is the largest e-scooter service in South America. This startup raised over \$270 million of capital.
FLASH	Founded in 2019, is a Switzerland micromobility startup from Delivery Hero raised over \$63 million of capital.
VOI	Founded in 2018, Europe's leading home-grown e-scooter operator from Sweden, VOI hat operates an e-scooter service in a 38 cities across 10 European countries, has raised an \$85 million of capital.
CIRC	Founded in 2018 as Flash, is an electric scooter startup in Berlin-based raised over \$55 million of capital. Operates in more than 40 cities across 14 European countries, in addition to United Arab Emirates.
TIER	Founded in 2018, is a Germany electric scooter startup raised over \$55 million of capital. Tier currently operates in over 40 cities across 12 markets worldwide.
SKIP	Founded in 2017, SKIP is a San Francisco-based dockless electric scooter startup raised over \$31 million of capital.
DOTT	Founded in 2018, is a Netherlands electric scooter startup raised over \$30 million of capital.
WIND MOBILITY	Founded in 2017, WIND is an electric scooter startup base in Berlin and Barcelona. WIND raised over \$22 million of capital.
SPIN	Founded in 2016, SPIN is an electric scooter startup that has raised a total funding amount of \$8 Million. They is one of the popular electric scooter service providers that is currently available in more than 19 cities in U.S.
BEAM	Founded in 2018, is Asian electric scooter startup raised over \$6,4 million of capital. Beam is focused on expanding transportation options in Asia (Singapore).

Benefits

E-scooters offer a variety of advantages for users in urban spaces. It's not hard to understand the benefits of electric scooters. Are e-scooters only fun? For a commuter arriving by train from the suburbs, facing a half or one-mile slog on foot to the office, or a tourist with only a day in a city, the devices present an easy solution: download the app, add credit card information, unlock one of millions of scooters parked nearby, and off you go. It is a particularly easy mode of transportation to book and pay for. Also, e-scooters present an opportunity to support local tourism, in both urban and more rural locations.

"Are they attractive enough that e-scooters will be considered an alternative to urban mobility transport?"

One of the biggest benefits is that e-scooters are dockless, as they can be left anywhere. And because they run on electric batteries, they allow users to feel good about making a climate-friendly choice. A survey conducted in 2019 of attitudes to use e-scooters in New Zealand cities with 591 persons showed 57% of e-scooter trips replaced trips that would have been made by active or sustainable modes (on foot, by bicycle, skateboard, or e-bike), 28% of e-scooter trips replaced a trip by private car or van, motorcycle, ride source vehicle, or taxi (Fitt and Curl, 2019). Also, the benefits of e-scooters can differ widely between geographic areas that are only a few blocks apart due to the differential access of these areas to transit lines and bus routes. The emergence of e-scooter options has inspired many cities to rethink the ways in which their transportation infrastructure might accommodate alternative modes.

Another benefit of e-scooters is the cheaper mode of travel. Also, riding an e-scooter doesn't need any special skills or license. It's also much faster to drive an e-scooter than a car on congested roads. The most-common pricing structure in Europe so far has been 1 EUR for unlocking the scooter and 15 cents per minute as rental time. In cities with higher income levels some operators like Lime and Tier increase prices up to 20 cents per minute.

"How can e-scooters be integrated into overall mobility transportation system?"

E-scooters offer cities another tool in fighting mobility deserts. As a flexible means of transport, e-scooters can play a key role in solving the "first and last mile gaps for the transit systems, filling the gap between a rider's home or destination and public transport stops, opening access to underserved populations." More generally, they also add more options to multi-modal mobility systems and provide better connectivity (Fig. 2).

Additionally, e-scooters are extremely efficient. E-scooters are an efficient way of traveling short distances using efficient and clean energy. Just for comparison, a fuel-powered car can travel a maximum of a mile on 1-kilowatt-hour of energy. However, 1-kilowatt-hour of energy is sufficient for an electric scooter to travel 80 miles. So, e-scooter options provide huge efficiency in terms of energy usage and reduce the dependency on fossil fuels (Hollingsworth et al., 2019). Compared to cars e-scooters are much cheaper. For example, the BMW Model i3, an electric car comes for around €34,950,00. You can buy 100 e-scooters high-quality ones for the same price. It is not yet known about the future of e-scooters. However, it is possible to see the great economic difference compared to cars. So, e-scooters are not only energy-efficient but also have lower costs of production. Also, e-scooters have brought that advantage of

Figure 2 First and last mile of e-scooters.

no noise and the vehicles are very quiet. They reduce the weight of CO₂ emissions not only while traveling but also during production. As a result, they are ideal for an economically and environmentally viable transport option.

Table 2 shows e-scooters cost compared to other transportation modes.

Challenges and Opportunities

In the past years, we have seen an avalanche of e-scooters in several cities, and it is apparent that these new means of transport have become the favorite of millions of people, and consequently the “cash cow” of micromobility. Even though e-scooters are a growing trend, it has its share of challenges.

“How should e-scooters be designed and controlled with regard to service concept, price, vehicle and infrastructure, in order to achieve the highest possible customer acceptance on the one hand and to achieve the municipal goals on the other hand?”

Some of the challenges are related to the infrastructure of the city, while others deal with regulations and safety or sustainability (Bekhit et al., 2019; Fitt and Curl, 2019; Todd et al., 2019). A lack of data and scholarly research on e-scooters also compounded these issues (NACTO, 2019a). The data ensure that municipalities can make informed decisions about what is happening on the public streets and how it might impact safety, health, equity, environmental outcomes, and the distribution of people and resources.

One of the main challenges for e-scooters is about safety (Bekhit et al., 2019). Perhaps the most controversial, and greatest pain point for city leaders is e-scooter operation on the streets and sidewalk. Collisions with both cars and pedestrians have sent thousands of e-scooter users and their unwitting victims to hospitals. Some of the misuse of the dockless vehicles can be chalked up to users’ unfamiliarity with the vehicles and the city’s regulation of their operation.

Sometimes injuries are minor, other times, riders face serious injury or even death. Every city has different rules about where e-scooters can be operated, and ultimately, it is up to the user to educate him or herself. E-scooter operators have also been engaging in various efforts to educate the public about local regulations and the dangers of riding on sidewalks with guidelines, like safety equipment and velocity.

Another important safety challenge is the helmet usage. Many e-scooter related injuries are directly tied to riders not wearing helmets. However, many users claim that the not use a helmet provides a lot of freedom but also leaves riders potentially unprepared and vulnerable. Representative surveys regarding the use of helmets, determined the risk of an accident. Examples of these violations include operating a scooter on the sidewalk, traveling opposite to the flow of traffic, being less than 18 years old, there being more than one rider at a time on a given scooter, and not wearing a helmet. The growth rates of injuries demonstrate the need to ensure that helmets remain available for users (Fig. 3A,B).

Another challenge inherent to e-scooter usage is that many communities lack the infrastructure for alternative modes. Each city needs proper infrastructure to introduce e-scooters. Many regulatory systems surrounding these new modes are not yet settled. If a city doesn’t have requirements like routes or parking spaces, the adoption of e-scooters becomes difficult. That’s the main reason the adoption of e-scooters is low in poor countries like Africa and developing well in countries like United States and France.

“How can we operate and prevent e-scooter vehicles from being parked where we don’t want them to? How do we modify our lanes to keep riders safe while also keeping enough sidewalk space for pedestrians?”

The proper requirements for e-scooter use is necessary so that people can travel safely without fear of accidents or injuries and see this mobility mode favorable. In Munich, Germany, the requirements of the use of e-scooters include: any person riding in prohibited locations (e. g., on the sidewalk) is subject to a €15 fine, which may increase if the behavior hinders (€20) or endangers

Table 2 Comparative transportation costs

Transportation system	Price ^a
Shared e-scooter	1€ + 0,15 min
Bikeshare	1 €/ 30 min
E-bikeshare	1 €/0,15 min
Personal car	€ 0,50/km
Car share	€ 0,30/min
Metro	€ 3,30 (short trip 1,50)
Bus	€ 3,30 (short trip 1,50)
Taxi	€ 5 up to 2 km

^aMunich Price (Germany).**Figure 3** Examples of restrictions to riders of e-scooters.

€25) others, or if it causes damage (€30) (AGORA, 2019). These fines are relatively low compared to other locations internationally like in France where the violations start from 35 euros and range to 135 euros. For example, in Washington DC, e-scooter requirements comprise: up to 600 vehicles to be re-evaluated quarterly; cannot travel more than 10 mph; must provide users with a free helmet within 14 days of request; if parked incorrectly, providers must move vehicles within 2 hours of notification.

These challenges have inspired many cities to commit to designated infrastructure that can accommodate alternative modes. Some cities like Atlanta, Canada, Portland and Washington DC, United States, and Sydney, Australia have begun to paint bike lanes in spaces previously dedicated to curbside parking spots or even created road barriers between e-scooters and bike lanes and vehicle lanes (Fig. 4A,B). These sorts of policies and actions create a more robust micromobility culture, by making e-scooters an alternative mode of transportation to be easier, safer and more efficient, reducing crash risk for all road users (PBOT, 2018; NACTO, 2019b).

Regarding the parking zones for e-scooters, if a city doesn't have requirements like lanes or parking spaces, the adoption of e-scooters becomes difficult. Many American cities like San Francisco, Washington, DC, Kansas, New York, Norfolk, and Los Angeles launched dockless pilot programs in order to improve the regulation system e-scooters (NLC, 2019; NY City Transportation Department, 2019). Most cities use short-term pilots and time-limited permits to explore options for shared bikes and e-scooters in their city in a controlled manner.

Examples can see in several cities. A pilot study launched in Washington, DC found that 8% of 181 observed shared dockless e-scooters and bikes were parked undesirably (DDOT, 2019). Another study in Portland, OR, 3% of 357 found e-scooters impeded ramps, curb cuts, or handrails, 5% completely blocked pedestrian movement, and 8% partially blocked pedestrian movement (Portland Bureau of Transportation, 2018). Last, a study in Rosslyn, Virginia found that 16% of 606 observed e-scooters not parked properly and 6% (36 e-scooters) were blocking pedestrian right-of-way (Owain et al., 2019) (Fig. 5A,B).

E-scooters have also proven to have a unique ability to create public anger and perturbation. Many cities experience negative feedback from residents and pedestrians about e-scooters being discarded carelessly in public spaces, such as sidewalks calling them "e-waste on the side-walk." Cities and providers require users to leave their vehicles in locations that do not block foot traffic or access points.

A challenge not less important concerns the equity in urban environment. In recent years, the urban mobility is challenged by innovative changes and new opportunities of transportation integrating into urban landscape with challenging operating conditions for the cities. However, most of the population and users don't have information about these transportation modes and its impacts. There is a lack of access to these items, which is one of the reasons why many people do not use an e-scooter. Several cities, such as Columbia, Ohio, and Washington, DC, are requiring e-scooters to deploy in underserved areas to ensure, these new pilots and programs align with their goals around equity. Additionally, the distribution of the fleet throughout the city should be balanced, so that it serves all communities equitably.

Figure 4 E-scooters and bike lanes.

Anticipated Future Impact

Since e-scooter vehicles arrived in several cities, local governments have struggled and been challenged to develop new methods to manage this transportation system. The rapid unexpected deployments of local government and the public elicited a range of responses from the different parties. Many cities crafted amenable regulations and pilot programs; others were less welcoming.

"How does the future of e-scooters look like?"

Without doubt, the future is promising. There's more than enough demand, and the promise is admirable. Thus, the question that really interests me is *how can e-scooters grow beyond its problematic introduction to truly become a harmonic service to a city and its residents?*

To start, e-scooters need to be dropped off in specific areas that represent a tidy solution to the city landscape. This means that they aren't in the sidewalk and not a danger to pedestrians and those with disabilities.

Economically thinking, we believe that improving people's mobility and optimizing economic and business cost (total cost, user cost) cities can take different approaches to cost recovery like using the revenue from e-scooters to fund a separate account dedicated to expanding alternative infrastructure. This requires a bond to cover the cost of removing broken or improperly parked scooters. Washington, DC, for example, is requiring a \$10,000 bond to cover the costs of removing broken or improperly parked scooters (NLC, 2019).

When it comes to regulation, we believe that improving regulated market access of the services providing high performance for users and operators. The municipalities should create a comprehensive permitting process for providers. This allows the city to regulate and monitor the deployment of e-scooters while also allowing providers to quickly roll them out. Providers have an amount of quality data on vehicle locations and trips, which can be critical to city governance decisions. Not only this data can help bolster safety and accountability efforts, but we will be also able to identify who is using these services, where they're going and when, and how well their current transportation infrastructure maps that information.

Regarding social aspects, we believe there could be maximizing participation, accessibility, and education of the population. An approach to provide these services to low-income residents, the municipalities should include diverse payment options and fare

Figure 5 Parking zones.

discounts and should reduce barriers to participation. E-scooters are also poised to promote equity by improving services to low-income and underserved communities. Additionally, there should be constant emphasis on balancing fleets, so that they serve all communities equitably.

The last point is improving safety and health. One of the major lessons learned from the short history of e-scooters that companies should encourage (but most of these not enforce) safety standards. That responsibility falls squarely on the city's shoulders. Understanding how to keep residents safe while allowing them to utilize these new services is one of the biggest challenges that cities will face. Safety means more than requiring riders to use helmets or imposing speed limits. It means re-evaluating the city's entire transportation system, especially for the non-users too.

Many citizens expect that municipalities to develop an antidote against congestion and pollution and e-scooters may be a way to provide a real, everyday alternative. However, in addition to boosting their business, companies in the industry can put more influence on management, taking a pro-active role in creating a real industry in major urban areas. Because of this, we consider e-scooter operators' participation along of the claims of the local communities and government. E-scooter operators will also engage in various efforts to educate the public about local regulations and the dangers of riding on sidewalks.

Conclusions and Recommendations

We conclude a set of recommendations cities can consider as they work to regulate the use of e-scooters. As e-scooters are relatively new to us, many municipalities are still at the early stage of discovering how e-scooter trips are distributed and how urban environments might relate to them.

So the question remains: "What can key players do to exploit the great opportunities of e-scooters in order to achieve the municipal goals of transport planning and to improve the overall system?"

Naturally, urban environment will become more crowded and the e-scooters can go a good solution long way to reduce the stress on existing transportation networks and offer an affordable and viable means of moving around. As cities grapple with increasing pollution and congestion, e-scooters provide a solution that can move more people in a cleaner way and makes efficient use of valuable public road space. Also, the e-scooters have also accelerated a discussion about road safety, and how cities must redesign streets to help keeping all road users safe. As a result, e-scooter operators have emerged as partners for cities looking to meet important sustainability and safety aspects.

The integration of public authorities with operators of e-scooters as a partner ensures that the legal framework, public welfare, social acceptance and networking between cities and countries. The integration will provide Governments with more information in how to conduct the regulations and disseminate information to the population and the countries opening the way for the mobility of the future. There is a huge lack of scientific data and body of knowledge about e-scooters. In order to build on this subject, there is a necessity for more scientific research and data, which will help understanding this industry better and provide better analyses. A combination of digital and physical infrastructure can help aid the conformity of users. This can be made compulsory by regulation. Hence, the authorities should in a position to build up expertise and contribute to the development of new mobility forms through funding together with partners from industry and science.

The e-scooter data sharing will eventually provide more information about rides and this will aid further development in the field. Only infrastructure like lanes and parking does not warrant many changes. But this is hard to accomplish without supervision, regulation and more personnel. Steps like use of helmets and indicators like velocity should be made compulsory for using e-scooters and can have a positive impact on safety. Additionally, licenses for e-scooters can be created to add an additional condition of accountability and conformity in all cities. Municipalities should regulate the number of operators, types of e-scooters implemented, and fleet size released on the street.

To conclude, many of the practices include dynamic recommendation, but much remains to be done.

Introduction

Railway stations are places, where trains are designated to stop. The location and design of railway stations depend on the:

- Kind and volume of transport demand, either for passengers or goods,
- Links with other stations,
- Kind of trains and scheduled transport services,
- Topography, land-use and environment,
- Population, economy, and transport policy.

At stations passengers may board and alight trains or goods can be loaded and unloaded. Station facilities collect and distribute passengers, who get on/off the trains via platforms, and may transship goods, respectively. As the classification, formation and blocking of freight trains is much more complicate than the (de-)coupling of passenger trains, passenger railway stations are segregated from freight railway yards. The design of freight railway service networks is not considered here and treated by [Crainic \(2020\)](#) in this work. For the geography of rail transport see [Dobruszkes and Moyano \(2020\)](#), while rail transport and territorial scale is further dealt with by [Monzon and Lopez \(2020\)](#) in this work. Railway traffic management approaches are discussed by Corman in this work.

Currently, the planning and choice of the place and design of railway stations is mostly done in an evolutionary process governed by political decisions. Transport, spatial, urban, and/or environmental planners analyze the performance of existing mobility patterns, traffic, and transport modes in order to develop alternatives to cope with growing demand, traffic congestion, and consumption of natural resources. Then, alternatives for station capacity extension at existing locations or new stations are evaluated by means of system performance criteria, costs, and benefits. Finally, local, regional, or national governments decide, which alternative to choose based on political preferences, budget, and constraints.

The planning process for railway stations consists is explained in the following sections:

- Analysis,
- System specification
- Geometric design,
- Timetabling,
- Simulation,
- Optimization.

Analysis

The analysis of railway stations describes their functions within the transport network, location in the city, transport flows, platform and track geometry, train operations, information, customer service, safety, and security. The network function of stations can be classified according to their network positions, rank and kind of train services. The station's strategic network position is generally divided into ranks according to the kind of trains calling there:

- Top level stations (Inter-/National trains; High-speed/Intercity trains),
- Middle level stations (Inter-/Regional trains; Express trains),
- Low level stations (Sub-/Urban trains; Metro/Subway trains).

Furthermore, railway stations are disaggregated according to their positions along the train line into:

- Terminal stations (Start/End of train lines)
- Intermediate stations.

The station's location in the city determines its accessibility, attractiveness, and design. Accessibility is measured as connection (in distance or time) with other modes of transport (walk, bicycle, taxi, bus, tram, ferry, air), infrastructure (road, river, sea port, airport), and whether it is barrier-free (step-less) for mobility impaired people. Accessibility to/from railway stations is calculated as generalized journey time from/to different (sub-) urban areas (Papa and Bertolini, 2015).

The attractiveness of railway stations depends on different factors, such as:

- Number, density and distance of residents', commuters' and visitors' population, jobs and schools in the catchment area,
- Transport access and egress modes, times, and costs,
- Connectivity, frequency, travel time and costs of train services to/from other destinations and origins,
- Existence of travel facilities and vicinity of commercial and recreation opportunities,
- Image, safety and security of the station and its neighborhood area.

The geometry of platforms and tracks respectively at a railway station can be classified according to its arrangement, use and levels into:

- Lateral platform,
- Central platform,
- Operation by line,
- Operation by direction,
- At-grade,
- Grade-separated,
- Stub-end tracks,
- Through tracks,
- Merging, diverging or crossing tracks,
- Tangent tracks.

Lateral platforms are simple to design and build, but need more space and equipment than central platforms, which require increased track spacing and track bending. Platform operation line by line is easier to design, less expensive to build and used independently, but less comfortable and efficient for transfer of passengers and train circulation than operation by direction (Figure 1). The latter one enables (almost) simultaneous cross-platform transfer between different lines and minimum train interval times.

Stations with grade-separated underground or elevated platforms and through tracks offer maximum capacity at high costs, can be situated close to city centers, generate high transport demand, and are indispensable for multiple long distance train operations of bigger railway networks and convenient transfer of passengers from/to urban and regional public transport lines.

Stub-end tracks are standard for terminal stations, but require many switches, complicated train routing, occupy much space and restrict track capacity. Through tracks are typical of intermediate stations, easier to design, less costly to build and enable maximum throughput. Terminal stations cannot be accommodated easily in densely built-up urban areas, require high cost of construction and are situated mostly at-grade, except underground or elevated metro terminal stations which are extremely costly and therefore restricted to few platform and stabling tracks.

The train movements in stations with multiple tracks are performed according to the timetable via route set-up and released by interlocking machines, as well as by fixed block signals and automatic train protection (ATP), automatic traffic control (ATC) or automatic train operation (ATO) systems. So far, ATO systems have only been successfully implemented on a growing number of driverless (sub-)urban metro lines, whose platforms are usually equipped with screen doors to protect waiting passengers from falling on the track. ATO is still neither available for long distance passenger trains operated on dedicated high-speed railway lines, nor on lines operated by both passenger and freight trains.

Timetables describe the scheduled arrival and departure times, as well as the platform track numbers of all trains at each station. The times between arrivals and departures of the same train indicate the scheduled dwell times at the platform. The interval time between the departure (and the arrival respectively) of the preceding and the following train on the same track or junction is called headway time. The frequency of trains per line is given by the total number of trains in the same direction divided by the length of the period considered (mostly per day or per hour). The scheduled mean headway time at a platform track is equal to the inverse of the train frequency.

The standard information provided at railway stations consists of the (planned/actual) arrival and departure times and platform track number of every train per kind of day and season, signage of entry, exit, platform number, other public transport platforms, taxi, ticketing counters or machines, toilets and other facilities. Timetable information is locally transmitted via printed tables, central and platform (video and/or digital) displays, as well as public address. Frequent updating of actual customer information and advice by station service personnel concerning train delays, canceled trains, platform track changes, quick public alarm and professional guidance in case of incidents, fire, accidents, attacks are essential.

Figure 1 Platform arrangement and track layout of railway stations operated by line or direction. (A) Three-track station at a branching point, (B) four-track station at a branching point; storage tracks are shown, (C) joint station of two lines, and (D) "Weaving station" of two lines with simultaneous two-way transfers. *Source: Vuchic, 1981, p. 420*

System Specification

The functional specification of passenger railway stations should contain at least a description of the following principal elements:

- Location, level (rank) and position in the railway network and line,
- Passenger transport design volume and capacity,
- Kind, train frequency and speed of line services per day in each direction,
- Maximum length, loading gauge (profile) and axle weight of rolling stock,
- Number, length, width, and level above top of rail of the platforms,
- Track layout with number, gauge, spacing, design speed, maximum gradient of through, platform, shunting, stabling, maintenance and workshop tracks, crossings, and switches,
- Level, spacing and voltage of overhead wires, catenary or third rail,
- Track capacity,
- Maximum evacuation time from platforms in case of fire, blasts, and disaster.

The passenger volume of railway stations mainly depends on transport capacity, frequency, occupancy of the kind of train services and the number of lines operated.

The track capacity is defined as the maximum number of trains that may in theory be operated over one track section per period, usually per hour or per day. The theoretical track capacity is unlikely to be reached in practice due to timetable and safety margins, synchronization of train arrivals and departures, and waiting times during operations. Track capacity of single tracks is measured in both directions, while for double tracks it is measured per direction. The minimum headway time between a pair of trains on a platform track depends on the:

- Sequence of train arrival, passing and departure or vice versa,
- Speed, acceleration, deceleration, and length of trains,
- Signaling and safety systems,
- Volume, density, spatial distribution, and speed of passengers waiting, alighting and boarding.

Geometric Design

The design of railway stations is governed by their functional requirements, available space, urban master planning, environmental, economic, and architectural considerations. The geometric design of tracks, stairs and platforms in stations is closely interdependent with the (vertical) levels of the top of rail, platform, horizontal alignment, gradient and cross-sectional spacing.

Timetabling

The operational program determines the design of the station's infrastructure, including the arrangement and number of tracks and platforms. Timetables can be either periodic or nonperiodic. Integrated periodic timetables for railway networks are characterized by almost simultaneous arrival, and departure times respectively, of the different trains at the principal nodes of the network at regular intervals to offer synchronized smooth passenger transfer between lines. A comprehensive review of timetabling and capacity estimation methods for stations with multiple tracks such as Stuttgart 21 is given in Hansen (2017). Queuing models have been applied to estimate the waiting probability and queue length of the planned high-speed and regional express trains on the approaching routes and platform tracks, whereas microscopic simulation runs of the scheduled train services have been performed in order to estimate the track occupation times, number of platform tracks required and operations quality.

Track capacity consumption is estimated analytically by the mean of the track occupation times divided by the mean of the scheduled inter-arrival (headway) times per period for each (platform) track (Eq. (1)). The estimated theoretical track capacity (performance) is given by the length of the considered period divided by the mean minimum headway time (Eq. (2)). The practical track capacity is estimated by adding the mean buffer time to the denominator (Eq. (3)). The buffer time is a time margin on top of the minimum headway time to reduce the propagation of train delays. The distribution of buffer times in railway timetables and its impact on track capacity and quality of operations was first described comprehensively in Schwanhäuber (1974).

$$\text{Track capacity consumption } \rho = \frac{tB_m}{tA_m} \quad (1)$$

tB_m : mean track occupation time
 tA_m : mean inter – arrival time

$$\text{Theoretical track capacity } C = \frac{T}{tH_m} \quad (2)$$

T : Time period [min]
 tH_m : mean minimum headway time

$$\text{Practical track capacity } C_p = \frac{T}{tH_m + tR_m} \quad (3)$$

tR_m : mean buffer time

The Union of International Railways (UIC) recommends certain levels of track capacity consumption per kind of train traffic and period (Table 1). The corresponding values for junctions in station yards are reported in Table 2.

Table 1 Recommended levels of track capacity consumption by UIC (2013)

Type of line	Peak hour	Daily period
Dedicated suburban passenger traffic	85%	70%
Dedicated high-speed lines	75%	60%
Mixed traffic lines	75%	60%

Table 2 Recommended levels of track occupancy in station areas by UIC (2013)

Type of node area	Concatenated occupancy rate	Additional time rate
Switch area	60%–80%	67%–25%
Track area	40%–50%	150%...100%

The minimum headway time is equal to the minimum inter-arrival time between two train paths considering their requested speed profiles. The minimum headway time is determined in the first block section of that part of the infrastructure which is used in common by both trains. The minimum headway time between a pair of trains following each other on the same track section is equal to the maximum difference between the end of the blocking time of the preceding train and the start of the blocking time of the following train (Besinovic et al., 2016).

The blocking time is defined as the time interval during which a section of the track is allocated for the exclusive use of one train and is therefore blocked for other trains (Hansen and Pachel, 2014). The blocking time of a track section depends on the operations program, timetable, routing of trains, signaling and safety systems, and is computed as the sum of the switch time for setting up the route and corresponding signals, the train's running time over the sight distance (usually 300 m), the approach time, the running time over the nominal braking distance, block length, train length, safety distance, and the time to clear the route (Eq. (4)).

$$\text{Blocking time } tB = t_{\text{switch}} + t_{\text{sight}} + t_{\text{approach}} + \frac{l_{\text{block}} + l_{\text{train}} + l_{\text{safe}}}{v} + t_{\text{clear}} \quad (4)$$

t_{switch} : switch time for setup of the route and signals, t_{sight} : running time over the sight distance, t_{approach} : approach time $\geq \frac{v}{2a}$, t_{clear} : clearing time, v : speed, a : nominal braking rate

The number of platform tracks needed is equal to the mean track occupation time divided by the mean minimum headway time per peak hour (Eq. (5)). The timetable quality can be measured either by the standard deviation of the scheduled inter-arrival times divided by the mean of the interval times (Eq. (6)), or the standard deviation of the track occupation times divided by the mean (platform) track occupation time per track per period (Eq. (7)). The latter values correspond to the variation coefficient of the scheduled train interval V_A , and track occupation times V_B respectively.

$$\text{Number of platform tracks } N = \frac{tB_m}{tH_m} \quad (5)$$

$$\text{Timetable quality } q_A = \frac{sdev tA}{tA_m} = V_A \quad (6)$$

$$\text{Timetable quality } q_B = \frac{sdev tB}{tB_m} = V_B \quad (7)$$

Track occupation of individual track sections in multi-channel stations:

$$\psi = \frac{n \cdot tB_m}{s \cdot T} = \frac{\rho}{s} \quad (8)$$

n : number of train paths per period, s : number of service channels

Simulation

Simulation of passenger flows in railway stations is used to study the behavior of people when getting on and off the trains in order to evaluate the performance and safety of design options for access/egress and passenger processing (to/from gates, main ticketing facilities, corridors, stairs, escalators, lifts, and on platforms (Zou et al., 2019).

Railway timetables are simulated to calculate the running time of planned train services and analyze the impact of train performance characteristics, timetable options, infrastructure alternatives, and train operations on station and network performance. Railway simulation approaches can be classified according to their kind, scale, scope and data processing into:

- deterministic or stochastic,
- continuous or discrete,
- macroscopic or microscopic,
- synchronous or asynchronous

models (Watson and Medeossi, 2014).

Simulation is deterministic if all parameters are defined by the user and do not contain any random components. Stochastic simulations are based on probability distributions of design variables and are used to investigate the system behavior if the design parameters vary like the fluctuation of transport demand, train running, dwell and headway times. Continuous railway simulation

models are applied to compute the train motion in time and space, while discrete timetable simulation models are used to calculate the change of state variables at fixed time intervals (arrival and departure) or events (signal at danger/proceed/start braking, route set-up/release, train order).

Macroscopic simulation models apply a simplified railway infrastructure model, where the stations are represented as nodes and the links in between as arcs. Microscopic railway simulation models describe the detailed infrastructure, train movements, state of signaling and safety systems and timetable as directed graph. Macroscopic infrastructure and timetable simulation models use a scale of kilometers in space and minutes in time, whereas microscopic simulation models represent the infrastructure topology in centimeters and time in seconds. Based on rules of operation, timetable designers determine minimum headway times in macroscopic simulation models as input, while the required safety margins are automatically calculated in microscopic simulation models according to blocking time theory.

Synchronous timetable simulation models continuously estimate and monitor the state of the infrastructure and position/speed/acceleration/deceleration of every scheduled train in the network simultaneously at short time steps (usually one second) in order to test timetable feasibility, robustness against incidents and safety of train operations at microscopic scale. Asynchronous (discrete) timetable simulation models are used during timetable design and construction to evaluate the impact of different train priorities, speed levels, train orders, routing, platform allocation on track capacity and system performance.

Optimization

Optimization models aim to maximize or minimize an objective in the presence of complicating constraints. Exact search methods include linear programming (LP) and some forms of integer (IP) and mixed integer programming (MIP) which allow only little flexibility and are based on simplifying assumptions. Therefore, many optimization models apply heuristics for problem solving. Optimization methods can effectively support the search for finding (near) optimal solutions of a variety of planning problems concerning design of railway station and network infrastructure, timetabling and train operations (Corman, 2020). In contrast, iterative station location and network planning is very time-consuming and may lead to suboptimal solutions.

Borndörfer et al. (2018) give a comprehensive overview of current modeling and basic algorithmic solution approaches for the optimization of strategic railway network assessment, infrastructure management, timetabling, vehicle, crew and traffic management. Various optimization models are proposed for strategic railway network line planning, tactical timetabling problems, and operational railway traffic management (train routing, rescheduling). A detailed review of transit network design and scheduling literature and terminology is done in Guihare and Hao (2008).

Public transportation and railway line planning approaches can be divided into cost-oriented models, passenger-oriented, game-theoretic, location-based models, and heuristics (Schöbel, 2011). In general, the network and number of travelers between each pair of origin and destination station (OD), a set of potential lines, lower and upper frequencies are assumed to be given, while the objectives, constraints and solution methods vary a lot. Instead of choosing a subset of lines from a given pool, the lines can be newly constructed respecting rules or satisfying certain criteria. A generic, bi-objective model for integrating line planning, timetabling, and vehicle scheduling is presented in Schöbel (2017). The problem of simultaneous design of rail rapid transit network and line planning is modeled by Canca et al. (2017).

Train timetabling problem (TTP) approaches for stations with multiple tracks and differ with regard to the granularity of the infrastructure (microscopic and macroscopic models of junctions, signaling and interlocking routes) and/or discretization of running, dwell and track occupation times, as well as the choice of objectives, constraints and solvers corridors (Burggraefe and Vansteenwegen, 2017; Cacchiani et al., 2016; Feng et al., 2018; Ghaemi et al., 2017; Pellegrini et al. 2014; Qi et al., 2016; Sama et al., 2017; Sels et al., 2014). Besinovic et al. (2016) propose an integrated hierarchical approach for the TTP, which combines microscopic and macroscopic models of the network infrastructure and train schedules.

Conclusions

The knowledge of planning, design, analysis, and timetabling of railway stations and networks has grown considerably. Innovative analytical, simulation, and mathematical programming approaches have been developed quickly and in practice during the past fifty years. Powerful and fast electronic data processing, transmission and computation technologies are used to increase the accuracy, effectiveness, reliability, efficiency and quality of railway planning and train operations. Moreover, a lot of intelligent mathematical algorithms and programming methods can support rational decision making on optimized railway network infrastructure investment, line planning, timetabling, train operations, and traffic management.

The main research challenge in this area is now to bridge the gap between academics, railway professionals and politicians by more customer-friendly, transparent, accurate and integrated modeling of passenger flows and train traffic in railway stations and networks. Easy-to-understand decision support tools for planners, timetable designers, railway passengers, operators, governments, and other people affected are required to find best solutions that balance common and diverging interests of stakeholders. Modeling the impact of multimodal transport flows in large networks on the design of sustainable railway transport infrastructure and mobility service networks which achieve the desired reduction of fossil energy consumption, carbon and noise emissions remains a big task.

Introduction

Rail transport in the world today plays a varying role according to the characteristics of the country (Table 1). In the EU, it plays a specialist role in the transport market, while road dominates. However, in some of the world's largest countries, rail plays a much greater role. The rail share of the passenger market is much higher in China and Russia than in average sized countries. Similarly the shares of the freight market in the United States and Russia are very high. Note the exceptions to this rule. Passenger mode share in the United States is very low due to competition from air and high levels of car ownership, and the freight share would be higher in China if not for the importance of coastal shipping.

The principal aim of this chapter is to establish what determines the role that rail plays in the transport market. In the next section we provide a brief and highly simplified overview of rail technology and its capabilities. We then examine the different markets for rail. We consider in turn long distance passenger, other passenger traffic, and freight. We then briefly consider railway organization before concluding.

Rail Technology

Rail transport comprises trains of vehicles running on a track, which guides them. Usually, the wheels and track are steel, although on some metro systems, particularly in France, they comprise rubber-tired wheels running on concrete. The advantage of steel is low friction; its main disadvantage as a result is that braking takes a relatively long distance, and thus except on low speed tramways some form of signaling is needed. Railways normally run on the principle that two trains should never be closer than the braking distance of the rear train (plus a safety margin, or "overlap," to cope with factors such as reduced adhesion due to rail surface condition, or worn brakes), and it is the function of the signaling system to achieve this. Traditionally, rail routes have been divided into sections called blocks, and the signaling ensures that trains are always at least one block apart and that the rear train is not traveling at a speed such that stopping within one block is not possible. This was achieved by lineside signals, which told the driver whether it was safe to proceed at full speed, safe to proceed at reduced speed, or whether he/she should immediately stop. More recently, such systems have been backed up (or replaced) by electronic signals transmitted to the cab, which would automatically apply the brakes if the train was deemed to be traveling too quickly to stop in good order before the start of the safety overlap.

On a system with lineside signals, the capacity of a line is determined by the distance signals are apart. For instance, on a line with 3 signaling aspects (clear, caution, and stop) trains traveling at full speed must be at least two block sections apart and must be able to stop within those two sections. The minimum headway between trains in minutes is thus the time a train takes to travel those two sections. The capacity of a section of line per hour is 60 divided by the headway in minutes. When calculating the capacity of a line we need to consider differences in travel times in different sections, and the stopping patterns of trains at any intermediate stations (Hansen and Pacht, 2014).

High speed lines (i.e., lines designed for speeds of 300 kph and above) invariably have signaling systems where electronic instructions are transmitted to the driver's cab rather than relying on sighting lineside signals. It is the wish of the European Union to see such a system extended, at least to all main lines, using the European Rail Traffic Management System (ERTMS). In its more advanced form, ERTMS will have moving block signaling, under which signals are transmitted continuously to the train, rather than at the beginning of fixed blocks. These signals show the speed at which it is safe for the train to proceed given the locations of it and other trains on the system. From this it is a small step to complete automation of train driving and many urban metros are already completely automated. However, unless the railway is completely segregated (e.g., in tunnel or elevated) it is necessary to have some way of detecting obstacles on an automated system.

Table 1 Rail mode share (%) 2015

	<i>Passenger km</i>	<i>Freight ton km</i>
EU	8.3	11.3
US	0.1	33.1
China	40.2	12.8
Russia	33.4	45.3

Notes: Passenger km are the sum of those by all motorized modes of transport, including for the EU all intra EU trips; other than this, international traffic is excluded. Rail includes metro, tram, and light rail.

Freight ton km are the sum of those by road, rail, pipeline, inland waterways, air, and sea including for the EU all intra EU traffic; otherwise international traffic is excluded.

Source: Derived from EU Pocketbook. EU Transport in Figures, 2018.

Having considered the capacity of a line in terms of numbers of trains per hour, we need to consider the capacity (for passengers, freight, or whatever) of each of those trains. First, we shall consider train length. Given suitable terminals, sufficient rolling stock, and haulage power, the principal determinant of permitted train length is the need for trains to pass each other, either in the same or opposing directions. For single-track lines, passing points will be created at which one train can be parked while another passes. Where, given its degree of importance, a train is deemed likely to be looped there for another to pass, the length of that loop limits the length of the train. The lowest of all such limits for the loops on the line gives the overall permitted length limit. Similarly, on a multiple track section, if a slow train has to be parked (in a loop or siding) so as not to delay a following faster train, the length of that loop or siding also feeds into the length limit calculation. For example, on a line where the only overtaking points are at stations, the published length limit for the line will be the length available at the “shortest” station. Trains longer than the published length limit can be permitted to run if they will never need to be overtaken (or passed on a single track line).

Second, the maximum height and width of trains is determined by the height of over-bridges and tunnels and the gaps to other structures including station platforms. Subject to this, it is feasible to run double deck passenger trains and double stack container trains (i.e., with a second layer of containers on top of the first). Passenger trains of up to 30 coaches run in countries such as China and freight trains of up to 20,000 tons in various places. France runs many high speed trains using two double deck units coupled together with a total capacity of around 1000 passengers, while high density suburban rolling stock with provision for standing passengers may accommodate many more. So a total capacity for a double track railway of 20–30,000 passengers per hour in each direction is perfectly feasible and some metros regularly exceed this.

Thirdly, we consider how much can be loaded onto each vehicle. The maximum weight of a rail vehicle is determined by the permitted axle weight of the route, which in turn depends on the strength of the rail used and the structures crossed (such as “under-bridges”). For example, in the EU the standard maximum axle weight is 22.5 tons. So a 4-wheeled wagon with tare weight 22 tons evenly loaded with stone has a capacity of $90 - 22 = 68$ tons. Railways built solely to move heavy freight use much heavier rail and more robust construction and so have much higher axle weight limits. Conversely, as the name implies, Light rail systems are much more lightly engineered and have lower axle weight limits.

Naturally, the capacity of any railway depends on the investment made and how well its operation is planned. Obviously railways require installation of track and (usually) signaling, and that is expensive in terms of first cost, maintenance, and renewals. On the other hand, they have a large potential capacity. For instance, a two-track main line signaled for 3-min headways has a potential capacity of 20 (similar speed) trains each way per hour. Normally a margin of capacity is left free for recovery from delays, but with 3-min headways 14 trains per hour is common and up to 18 is practical as long as the system runs reliably. Given their relatively low speed, metros often have lower headways of the order of a minute and correspondingly higher frequencies than this.

Very high frequencies of service are generally only possible where all trains have identical characteristics in terms of speed (inclusive of station stops), acceleration, and decelerations. Otherwise a fast train following closely behind a slow train would very soon catch it up and be delayed, unless there were facilities for overtaking. It is clear that a large gap must be left before a fast train may follow a slow train if it is not to be delayed. For instance, suppose in the example of a two track main line signaled for 3 min headways fast and slow trains follow each other for 10 km (the slow trains may be freight, or passenger trains making intermediate stops); fast trains take 6 min; slow 20 min. If fast and slow trains alternate, capacity is reduced from 20 trains per hour to only 6 trains per hour, with departure and arrival times as follows: [0, 6], [3, 23], [20, 26], [23, 43], [40, 46], [43, 63] then [60, 66], etc. Capacity is also reduced by junctions (unless these are grade separated to avoid conflicting movements on the level).

On lower volume routes, the cost of track and signaling may be reduced by using a single track, but this has the disadvantage that trains in one direction have to enter a passing loop for trains in the opposite direction to pass. It is thus the travel time between passing loops that dictates the capacity of the system. Because of the delays to trains at passing loops and the risk of late running trains in one direction delaying those in the other, single track is rarely used for routes with more than 1 or 2 trains per hour in each direction.

Trains themselves may comprise a locomotive pulling passenger coaches or freight wagons or (mainly in the case of passenger trains) self propelled vehicles, which may be coupled to form longer trains (multiple units). In either case, they may be powered by steam, diesel, or electric traction. Except for short distances, where batteries may be used, electric traction requires provision of

current by means of overhead wires or third rails, incurring a capital cost roughly proportional to the length of track electrified. On the other hand, electric traction provides a clean source of traction at lower weight relative to its power and with lower maintenance and typically fuel cost than diesel. These benefits are roughly proportional to the number of trains run. So the case for electrification depends on the density of traffic; electric traction is the norm on more densely used railways.

Given the high capital cost, railways generally require high volumes of traffic to be economically viable. Stations are also expensive and stopping at a station slows the train and reduces capacity of the line. Therefore typically there will be a limited number of stations and freight terminals, and a need for passengers and goods to be taken to them by another mode, compared to the door to door convenience of road transport (although some freight transport does move direct between private sidings). As a consequence, rail transport will only be chosen when there is enough advantage (in terms of cost or speed) in using it for the trunk part of the journey to justify the cost and inconvenience of the feeder journeys and transfers between modes. This tends to mean that rail is more competitive with road for longer journeys.

Long Distance Passenger Trains

Traditional long distance rail services operate at up to 200 kph, giving a commercial speed usually not more than 150 kph allowing for starting and stopping. Many are slower due to constraints of the infrastructure, particularly curvature. But there is also time involved in getting to and from the station and waiting for the train. Even if that is as little as 1 hour, it still means that a 150 km journey by rail will take at least 2 h. If door to door road transport on high quality roads is available, such that car transport can average 100 kph door to door, this journey may be undertaken more quickly and conveniently by car; it is only for journeys above 300 km that rail will be quicker (Fig. 1 F). In this situation, unless road transport is more expensive than rail, it will only be those without access to a car or who value rail for other reasons (such as comfort or the ability to work on the train) that will consider rail. Where road infrastructure is good, even bus transport may be able to compete with rail on journey time, especially in cases where rail speeds are substantially below 200 kph. Of course, it is not usually possible to average 100 kph by car and certainly not by bus. Usually, there will be a part of the journey on lower quality or congested roads and sometimes the main roads themselves will be congested or of poor quality. Thus the ability of rail to attract passengers who could use car or bus transport depends very much on not just the quality of the rail service but also that of the roads.

Use of air transport usually involves a longer journey to and from the airport than for rail, plus much longer at the airport going through security and waiting for boarding. Suppose that the sum of these times is 2 h and that the flight time is typically half an hour, increasing little with distance. Then traditional rail will be faster than air door to door for journeys of up to 225 km, but beyond that air will start to compete on journey time, although many passengers seem to regard rail as more comfortable and convenient than air so it may be only above around 300 km that air starts to become important.

On some routes new high speed lines have been built with a maximum speed of up to 320 kph. Suppose that the rail service is provided by a new high-speed line with a commercial speed of 250 kph. This will enable rail to dominate other modes in terms of journey time over a wide range of medium distances. Even on the assumption that car can average 100 kph, rail will be faster than car for distances above around 170 km. More importantly, it will be faster than air door to door for distances of up to 375 km. In fact, evidence (Table 2) suggests that high speed rail can compete with air for greater distances than this; typically where rail station to station journey time is 3 h, rail has more than half the combined air-rail market and a substantial share at 4 h. This may relate to a distance approaching 1000 km. However, this evidence comes from Europe and Asia, where cities are dense, well served by public transport and therefore the central railway station is more convenient than the airport for most passengers. It might not apply to the less dense cities of North America and Australia.

Figure 1 Breakeven distances for journey time by intercity rail.

Table 2 Rail share of rail/air market and rail station to station journey times

Corridor	Year	Rail Travel time	Rail share (%)
Paris–Brussels	2006	1 h 25 min	100
Paris–Lyons	1985	2 h 15 min	91
Madrid–Seville	2003	2 h 20 min	83

Air (500 km flight) at 75% load	0.100
Electric high speed train at 70% load factor (British mean electricity mix)	0.050

Source: Derived from CILT, 2011.

Of course, the above are only examples. Circumstances differ, and there will always be some individuals for whom the rail station or the airport are more or less convenient than assumed above. But these simple examples do illustrate that conventional rail struggles to compete when faced with air services and high quality uncongested roads. It may play a much greater role in the long distance travel market where roads are congested or poor quality, or where car ownership is low. High-speed rail is likely to be competitive for medium distance journeys even where roads are high quality and uncongested and air services exist. Rail may also offer benefits in terms of reduced congestion and environmental benefits including reduced global warming (Table 3 gives estimates of emissions for Britain, at a time when coal and gas were still extensively used for electricity generation; as electricity production is decarbonized so the advantage of rail will rise). It should be noted that, with the sort of load factors achieved on the French TGV network and Eurostar services between London and Paris, high speed rail still has an advantage over car, and more so air. But of course, high-speed rail is very expensive to build (typically earlier routes in Europe cost 5 m–30 m euros per route km, with more recent routes tending to cost more as environmental standards tighten) and requires a substantial volume of traffic to be economically justified.

Other Passenger Traffic

Here we look at commuter services into large cities and cross-country services linking smaller towns to cities and to each other. They offer advantages to users over buses in terms of comfort and speed, especially where buses are on poor quality or congested roads, and similarly may attract traffic from car, relieving congestion, and pollution. But they may be very expensive per passenger where volumes are low. Thus they are typically only an economically viable option, even in social cost benefit terms, where volumes are relatively high, particularly into large cities.

Metros are rail systems found in large cities, usually run underground in the city center and operate at high frequencies with frequent stops. By contrast, trams generally operate on street in mixed traffic. Light rail is somewhere between the two, able to run on street, though usually with reserved lanes or priority over other traffic, but also with sections on segregated track or in tunnels. This may make it substantially cheaper to install than metros or conventional railways (Grimaldi et al., 2019).

Table 4 summarizes the capabilities of the alternative modes. Again, circumstances differ and it is possible to argue with the specific figures given for speed and capacity, but the pattern is clear: rail tends to have advantages where the desire is for high speeds (usually only needed where distances are longer) and high capacity. Again these factors dictate a particularly important role for rail in

Table 4 Characteristics of different urban public transport modes

Mode	Capacity of vehicle/train	Headway (mins)	Hourly capacity (000s)	Commercial speed incl stops (kmph)
Ordinary bus	75–100	1	4.5–6	20–30
Busway	60–75	1	3.6–4.5	60
Articulated bus	75–150	1	4.5–9	60
Bus in convoy	70–105	8 s	16–27	20
Tram	150–180	1	September 22	20
Light rail	180–210	1.5	July 25	30–40
Metro	400–800	1.5	16–32	40–50
Heavy rail	1000	March 2	20–30	50–60

Source: Adapted from *CILT*, 1996.

large cities. But segregated busways may rival rail where there is space to fit them in, and do have the advantage that buses can leave them in the suburbs to serve places to which it would not be economically justified to build a fixed track.

Rail services other than inter city almost invariably need subsidies to survive (though Japan, with its exceptionally high population density, and high costs of motoring and parking, has extensive regional and commuter services that are unsubsidized; these do often benefit from the involvement of the parent company in property markets). Governments often regard such subsidies as worthwhile because of the resulting reductions in congestion and pollution from cars, particularly as only a few cities worldwide have appropriate systems for charging cars for these costs. More recently there has also been a great deal of interest in the wider economic benefits of urban and suburban rail, with a belief that they raise productivity and attract economic development, leading to a further argument for subsidizing rail.

Freight

Traditionally, a large proportion of rail freight traffic has been handled by wagonload services, whereby individual wagons containing consignments for separate customers are loaded at terminals, taken to marshalling yards to be shunted into trains for a yard near their destination, and remarshalled into trains for the destination terminal. Such services were typically slow and unreliable, particularly if freight had to be transhipped from and to road transport for the collection and delivery at each end. While such services may be economically worthwhile if the speed and cost of rail for the trunk haul is well below road, these services have been in severe decline in Europe in recent decades. Usually they are only competitive for long distance traffic, such as can be found in North America.

With the growth of containers and swap bodies, a more efficient way of transferring freight between modes has come to dominate unit load traffic, and if the containers are transferred at large terminals then a more extensive range of through services without intermediate marshalling becomes possible. In the case of maritime traffic, much is already in containers and has to be transhipped between ship and another mode at the port in any case, so rail is more competitive for this than for purely domestic traffic.

Where volumes permit, there has also been a concentration on running complete freight trains for a single customer without intermediate marshalling. Typically this approach is used for bulk commodities such as coal, ores, stone, and oil. Where the train is running between private sidings at the premises of the customer and their supplier (for instance coal from a coal mine or a port to a power station), rail is competitive for this traffic over any distance.

A typical rail journey consists of some or all of the components illustrated in [Fig. 2](#).

By comparing road and rail costs for journeys of differing distances we can establish the breakeven distance ([Fig. 3](#)). For any distance shorter than the breakeven distance, road haulage charge is likely to be cheaper, but for distances over the breakeven distance rail should offer the best price. Breakeven distances are affected by the type of rail journey considered and the types of goods being hauled. Breakeven distances do not take into account the quality of service offered by each mode, with road generally being favored all else equal.

[Fig. 3](#) shows distances between 200 and 425 km, and compares road costs with 3 rail scenarios. The bottom line shows a private siding to private siding movement, with no marshalling costs or collection and delivery costs. It is always cheaper than road, but may not be so convenient. The top line shows a traditional collection and delivery movement. There are four marshalling operations, two lifts, two rail trip legs and road legs at both ends of the journey. For all distances shown it is much more expensive than road, with breakeven not occurring until around 1000 km. In the middle of the diagram is shown the total road cost line intersecting at around 300 km with the cost line for a movement from private siding to delivery point. This journey involves two marshalling operations and one lift, and a rail trip leg and road leg at the collection end of the journey. Rail is then seen to be competitive on price above this breakeven distance of 300 km. In each case we assume the trunk rail leg to be 20 km shorter than the overall road journey distance, and where applicable, the road collection/delivery distances to be 10 km and each rail tripping movement to be 30 km.

Relative costs will vary over time and from country to country so, although based on real UK data, this diagram can be taken to be nothing more than illustrative.

Figure 2 Components of a rail freight journey. Source: Fowkes et al., 2006.

Figure 3 Illustration of rail and road costs by distance for a given payload. Source: Fowkes et al., 2006.

In many countries, bulk traffic is in decline, and the growth areas are services and high value manufactured goods, which need to be delivered on a just-in-time basis. This is a challenge for railways, but intermodal services are a growth area with the greatest potential for rail freight. Rail freight is typically not subsidized, although in some countries it pays only its marginal cost to use lines mainly dedicated to passenger services. Obviously an important factor determining its profitability is the strength of the competition from road freight, which depends both on the quality of the road system and on the system for charging for the use of roads. While the European Union favors a distance based charging system differentiated according to both the impact of the vehicle on the roads and on the environment, few countries have so far introduced such a system.

Organization

In many countries, railways were originally built by private companies but there are now few countries where rail infrastructure is privately owned. It does remain the case that most railways are privately owned in North America, where railways are predominantly used for freight, and in Japan, where the three largest passenger companies have been privatized after many years of public ownership, and where there are also many privately owned smaller commuter railways. These privately owned railways run largely without government subsidy, freight traffic in North America and passenger traffic in Japan being dense enough to support this. However, in both cases services for the minority form of transport—passenger in North America and freight in Japan—are operated by government owned companies over the tracks of the private companies.

Some of the largest railways in the world—in India, China, and Russia—remain government owned vertically integrated companies. But in Europe, while infrastructure remains a government owned monopoly, it is the policy of the European Union

to encourage competition in the provision of train services, either by open access entry (typically some 30% of freight traffic is handled by new entrants while a handful of countries—notably Italy, the Czech Republic, and Sweden—have significant open access entry in inter city passenger services) or by franchising by means of competitive tenders (here Britain, Sweden, and Germany are the main users of this approach) (Thompson, 2003). There is also experience of franchising freight services in South America, where long vertically integrated franchises have been used as a way of revitalizing collapsing government owned freight railways.

Conclusion

Rail transport still plays a very important role in freight and/or passenger transport in some of the largest and most important countries in the world. In many other countries, it plays an important role in specific markets, such as passenger traffic into and between the largest cities and the inland collection and distribution of maritime containers. Rail transport is particularly suitable for longer distances and for larger volumes. While in the past, railways were almost invariably government owned outside North America and Japan, there is now a greater variety of organizations, with private sector open access operators or franchisees playing a bigger role in the provision of rail services.

Revolution or Continuity?

Questions concerning continuity and discontinuity are often asked in social sciences. The field of transportation economics makes no exception. For some historians the railways are part of a continuous process of improvement of transport and communications that accelerated with the first industrial revolution (see [Atack, 2019](#) for a discussion; [Fogel, 1964](#)). After all, railways were a combination of already known principles and techniques, which competed with already existing transport modes. Horse-drawn railways over wooden tracks to transport coal from coal deposits are clear predecessors of modern-day railways. The improvements that Richard Trevithick developed at the beginning of the 19th century, among which the use of high-pressure engines and iron tracks, gradually led to the first modern locomotive.

For other historians instead, the development of railways was more than that, and in fact a true transport revolution (see [Atack, 2019](#) for a discussion; [Rostow, 1960](#)). The quantitative and qualitative level of the changes and the intensity in which they were integrated and institutionalized was truly revolutionary. From a technological point of view the extraordinary novelties brought by the railways are evident, in particular if we refer to locomotives. The commitment of capital to build the railways was unprecedented ([Chandler, 1977](#); [Mitchell, 1964](#)). And the engineering challenges to build railways in mountainous areas dwarfed even those linked to the construction of canals, which represented an important ingredient of the first industrial revolution. From the physical point of view, not just the speeds, but also the strict scheduling that railways offered created true networks of transport and communication on the national scale. Due to the railways, many countries had to switch from many regional time zones to one national system ([Smith, 1976](#)). The railways also were the first large-scale technical system that triggered a total turnaround of economic interests, stimulating enormous financial investments. They influenced the structure of the early mature capital markets, inducing modern stock exchange practices and favoring the invention of new financial products, although also creating new stimuli for speculation and the creation of stock market bubbles. And, obviously, railways changed the geographies of the world. They influenced population density patterns and the concentration of entrepreneurial capital as well as the opening of new territories to cultivation and residential living ([Alvarez et al., 2013](#)).

The railway became a symbol of progress in itself. Few objects visualized progress in the way the railway did, standing for the complete disruption of the relationship between man and space, developing a new concept of mobility. Steam, iron, coal, and the genius of man that pushed the boundaries of technical knowledge ever further: all this finds its ideal synthesis in the picture of a running train, as in celebrated paintings such as William Turner's *Rain, Steam and Speed* (1844), and John Gast's *American Progress* (1872), where trains almost literally push civilization forward. What used to be far away and uninhabitable was no longer so thanks to the train; the formerly impossible was brought into the sphere of everyday opportunities.

The Debut: Stockton-Darlington

In the English case, the introduction of the railway linked with the economic needs of an already industrializing country. In other countries, the reasons for railway building often included political and cultural reasons, alongside economic ones. These could be linked to desires for prestige, for creating unity and a national identity (railways as an instrument for nation-building), direct military purposes or general sociocultural modernization.

In England, the opening of the Stockton–Darlington line on September 27, 1825 is commonly considered the first act of the railway era, although on part of the line stationary steam engines were still used to pull wagons. The locomotive used in this occasion

was built by George Stephenson, reputedly the father of railways, and had the simple name of *Locomotion*. It traveled the route at an average speed of 20 kilometers per hour. On the inaugural train, as reported by enthusiastic chronicles, at least 500 people mounted the train, partly on board and partly clinging outside the 33 wagons. Four years later, in 1829, the other major event of the first railway era took place: the Rainhill race. A speed race among locomotives was organized a few kilometers outside of Manchester. Stephenson, now at the helm of his famous *Rocket*, won the 500 Pound Sterling at stake. The *Rocket* towed a convoy of twenty wagons at an average speed of 25 kilometers per hour; in some places the train touched almost 50. Stephenson won by virtue of the introduction of a 2-meter long tubular boiler built by the French engineer Seguin. The following year the entire line between Manchester and Liverpool was opened, including a viaduct with 9 arches with a height of almost 22 meters. Around the same time, Stephenson founded his first locomotive factory. Although euphoria was first mixed with mistrust, the success of the railways was enormous and in a few years the country was crossed by numerous lines, built by competing companies. The lines were not yet integrated into a proper network, but remained rather fragmented.

The railways quickly conquered continental Europe as well, despite resistance of those with opposing interests, the huge effort to raise enough capital and technical difficulties. More or less everywhere, the first lines were short and still had a suburban character. By 1845, however, already more than 5,000 kilometers were constructed on the continent and networks were gradually developing.

The First Developments

In Great Britain ownership of the railways was private (Mitchell, 1964). The initiative was left entirely in the hands of private individuals. In 1837 there were already around a hundred railway companies active in Great Britain. In 1850, just 25 years after the opening of the Stockton–Darlington line, no less than 10,000 kilometers of railway lines had been built.

In continental Europe, private capital was certainly important, but it was often accompanied by state planning, control and often financing (Fremdling, 2003). In some countries, such as in France and in Belgium, this was true almost from the beginning. In others, such as The Netherlands, the state stepped in when railway construction seemed to lag behind other countries. In Germany and Italy the railways were quickly assigned an even more crucial role by the state, namely as a vehicle for national unification (Schram, 1997). Normally, a myriad of small companies played an initial role in the construction and management of the lines. Quickly, a process of consolidation and concentration developed, however, resulting in more robust corporate realities.

The various national networks developed in different formats, depending both on geographical and orographic reasons, on the size of the spaces, on the territorial distribution of the population (population density), on the kind of political and institutional system. Sometimes, reasons of centrality of the city capital prevailed. In Spain this led to the formation of a radial network focusing on Madrid.

Technological and Labor Issues

In the first phase, engineering techniques made giant strides. Civil engineering, locomotives and rolling stock all improved. Britain and Belgium were forerunners. Engineers and contractors of British railways stood out in particular. They traveled around Europe with their skilled workers, exporting knowledge of which they were the first depositories. George Stephenson and Isambard Kingdom Brunel were the most requested names, but Mackenzie, Samuel Morton Peto and Thomas Brassey were big names as well. Railway created thousands of new jobs, related to new constructions and maintenance of both the network and rolling stock.

The diffusion of the railways represented in many ways the definitive consecration of technology. From a technological point of view the locomotive was an extremely sophisticated product. The question of the most efficient and effective traction system kept generations of engineers busy. Great progress was achieved with speed, even though fuel efficiency was as important as speed: in 1890 a French locomotive reached 144 kilometers per hour. In 1879 the first electric locomotive was presented in Berlin.

In 1869 Westinghouse developed another breakthrough innovation with the air brake. The driver could now operate simultaneously the brakes placed on all the carriages by means of an air duct that originated from the locomotive. The automation of signaling really started off in 1872 with the system of automatic closure of the signals along the railway sections. Equally crucial was the remote control of signaling, based on the electro-magnetic telegraph. Its trajectory of development is strongly linked to that of the railways.

Way less visible, but allegedly as important, was a breakthrough in the materials used. Steel rails, more durable and consequently cost effective, replaced gradually iron ones. Toward the end of the 19th century carriages were made of iron and steel as well, leading to the demise of wooden ones.

The introduction of refrigerated wagons made transport of perishable goods, such as meat, possible. This allowed revolutionary economies of scale to be reaped in the meat packing industry, and Chicago to become the “hog butcher to the world” (Cronon, 1991). Lighting and heating in the train were taken care of right away: first based on vegetable oil, then gas and finally electricity. This allowed comfortable passenger travel. In the same direction went the adoption of the sleeping car, originally created by George Pullman, also in Chicago.

The Local and the National

The railways allowed a different spatial organization of economic activities, both on the national and the local or regional level. The railways were crucial in the process of spatial market integration (Donaldson and Hornbeck, 2016), and contributed to reversal of economic imbalances, as natural protection of less efficiently producing areas fell (Enflo et al., 2018).

The influence of the railways on urban development is diverse (Duranton and Turner, 2012; Roth and Polino, 2003; Schwartz et al., 2011). It ranges from the unhinging of traditional urban networks, to the development of railway stations as primary objects of architecture and urban planning. The development of railway networks in the 1880s and 1890s in urban areas often coincided with the demolition of traditional protective walls. This gave space to build huge, now monumental, railway stations on the outskirts of traditionally built-up areas, including related railway quarters with, for example, hotels (*hotel terminus*) and residential quarters for railway employees. In many cities, the 19th-century railway station is still a symbol of the power of progress, a temple of technological advancement, and a privileged field of experimentation by generations of architects and engineers called upon to design a radically new building.

The Maturity Phase

What is commonly called the second industrial revolution (conventionally, 1870–1914) also represents the stage of railway maturity. At the end of the 19th century, with an endowment of some 35,000 kilometers of railway lines, Great Britain was still among the leading countries. On the continent, however, France (40,000 kilometers) and in particular Germany and Russia (50,000 kilometers each) had surpassed Great Britain. Even British India had a larger network than the colonial power itself (39,000 kilometers). These countries were dwarfed, however, by the United States.

The dominant railroad country in the 19th century clearly was the United States. It had been an early starter as well with, already in 1840, twice as many railroads as Great Britain (4500 kilometers). In 1860 the network reached the Mississippi and in 1869 the connection between the Atlantic and the Pacific coast was completed (“from the sea to the sining sea,” as the adage goes), when in Promontory (Utah) the tracks of the Union Pacific Railroad were linked to those of the Central Pacific Railroad. In 1900 the network had grown to an almost unimaginable 311,000 kilometers. This was more than all European countries together. Although the expansion took place in more or less the same time as in Great Britain, the latter still supplied a lot of the necessary financial capital (Fenoaltea, 1988). Railways were first built to meet the demand for transport of agricultural products, such as grain and livestock, but the railways also created patterns of industrial growth by opening up the country.

The same would play a role in Russia, another country characterized by huge territories (Haywood, 1969, 1998). In 1855, four years after the opening of the Moscow-Saint Petersburg line, the network consisted of almost 1,200 kilometers. The railways represented for a strong stimulus for the industrialization of Russia, and, more generally, an opportunity for its modernization. The Russian metallurgical sector responded to the demand for iron and steel for rails and equipment. However, the country needed to look abroad to obtain the necessary financial capital. Between 1866 and 1890 the Russian network increased tenfold. Territories of more recent acquisition such as the in the Caucasus and the regions toward the Caspian Sea were integrated in the national domain by means of railway building. The line that ignited the imagination of contemporaries more than any other, however, was the Trans-Siberian. It was built between 1891 and 1903. Russia used it to effectively conquer its eastern territories, significantly consolidating imperial political power and with the purpose to settle the Siberian plains with Russians. At the same time it responded to an economic perspective for the transport of cereals and the potential exploitation of oil reserves.

Technological progress continued in the maturity phase of railways. The application of compounding and super-heating to steam locomotives reduced fuel and water consumption, and lowered the weight-to-power ratio, a standard index of technological progress (Ciccarelli and Nuvolari, 2015).

Regulation, Standardization, and International Agreements

The most significant change in the maturity phase concerned corporate finance and investment. In the second half of the 19th century new ways of supplying money came forward. The needs of large infrastructural projects innovated the financial system: from the adventurism of the early years, the world of railways had moved toward growing stability. If the commitments were too costly and the risks too large, the state often got involved (Bogart, 2013). In Germany, Romania, Serbia, and Bulgaria the state nationalized railway services from the second half of the 1870s. In Austria, Denmark, the Netherlands, Russia, and Switzerland the government started buying or constructing the main railway lines. Even where the railway sector was managed as essentially a private business governmental control and regulation became standard practice. Slowly, the idea that railways were a necessary social service and consequently a prime responsibility of the state was making its way.

As railway networks became more integrated, also at the international level, problems arose concerning the standardization of tracks, equipment, signaling, and organization (Carreras et al., 1995). From the 1870s an international regime of regulation of the various technical and commercial issues made its way. Technical integration in Europe, as in other continents, took many forms; overall it was an expensive and not at all easy process, hampered also by persistent political fragmentation (Federico and Sharp, 2013).

The first major problem that needed standardization was that of gauge, first between companies and later between countries. The increase in trade flows also pushed toward simplified customs procedures and in the use of wagons in international service. In 1872 the *Conférence Européenne des Horaires des Trains des Voyageurs et Services Directs* was created in Bern, Switzerland. It was an international organization with the aim of coordinating international connections. Shortly thereafter a complementary technical unit was created, the *Conférence Internationale pour l'Unité Technique des Chemins de Fer*. In 1922 the *Union Internationale de Chemins de fer* was erected in Paris (the website <https://uic.org/>, last accessed December 2019, provides a wide set of publications and data covering the more recent decades).

The Journey by Rail

The diffusion of railways introduced a fundamental change in the idea of travel and allowed the birth of railway tourism (Schivelbusch, 1986; Smith, 1998). This would experience its greatest expansion during the 20th century. The train offered itself as the ideal environment for pleasure trips. It facilitated traveling to reputed places of pleasure, while at the same time constituting itself as a tourist attraction as well. The rise of tourism as an organized economic activity took shape with the advent of the railway, roughly between 1830 and 1914. Everywhere in Europe railway companies were equipped for Sunday trips and inaugurated tourism policies. Since 1848, international pleasure trips were planned. The concept of holiday abroad is contemporaneous to the early diffusion of trains and the first travel agencies—the most famous of which was Thomas Cook—made their appearance and organized trips by rail. The tourism factor ultimately influenced the creation and subsequent exploitation of an integrated international rail network in terms of increasing the number of trains, choosing routes, coordinating schedules, increasing travel comfort, and speeding up transfers. Being comfortably seated in the compartment for a long time led to the spread of the habit of reading, which in turn caused a thriving travel literature to develop, among which the railway guides themselves. The most famous were Baedeker, Murray, Bradshaw, and the French Guide Chaix. French publishing house Hachette even inaugurated a specific series, the *Bibliothèque des chemins de fer*, specifically designed for rail travel. In 1889 the circulating library for travelers was tested on the Austro-Hungarian Empire railways, thanks to which it was possible to borrow books at each station and return them at a different one.

In 1883 the first trip took place of a train that would soon become legendary, the Orient Express. It was conceived by the *Compagnie Internationale des Wagons-Lits* and started in Paris, to go through Munich Vienna, Giurgiu (Romania), and the port of Varna on the Black Sea. From there, the final bit to Constantinople was done by boat.

The Semmering was the first true Alpine railway. It was part of the link between Vienna, the capital city of the Habsburg Empire, and Trieste, with its port on the Adriatic Sea. The line was completed in 1854. There were 15 tunnels and 16 long viaducts on the line. In 1998 it was declared a Unesco World Heritage site.

Many were also the failures, however. In particular in Africa, a number of projects did grab the imagination, but not the necessary financial capital to be successfully completed. The Trans-Saharan railway, for example, was long studied by the French colonial powers, but never realized. The same happened with the famous Cape to Cairo line, which was conceived to link and integrate a series of major British colonies in Africa, such as South Africa, Kenya, and Egypt. In the 21st century, China has taken up the challenge again of building railways in Africa, also to strengthen its economic and political influence.

In the 1870s, the newly unified Germany started considering the building of a railway line connecting Berlin to the (then) Ottoman Empire city of Baghdad. It was not just geopolitical motivation that drove Berlin to this project, but also the oil fields of the region until then mainly exploited by British and American companies. When the railway line finally opened in 1940, after endless political and financial difficulties, the world of transport had profoundly changed, however.

The 20th Century Decline

Rail transport maintained its prevalence over other forms of transport in the early decades of the 20th century. Between 1900 and 1915 the world network grew by almost 40%, so that at the start of the First World War more than one million kilometers of railway lines were in operation. Growth continued until the Second World War, but at a much slower pace: from 1920 to 1940 the increase was only 10%. The global network kept growing until in 1960 a total of more than 1.2 million kilometers was in existence. In many of the early adopting countries, however, the decline had already started at an earlier time: in Germany and the United States in 1915, in Great Britain in 1925, and in most other Western European countries around the 1930s. The rise of automotive transport (private cars, lorries, coaches) was the prime cause. It led to a clear decline in the use of the railways for public transport. Thousands of kilometers of lines, often the ones that were built as the last extensions of the network, were abandoned for a lack of passengers and consequent low profitability. Lately, abandoned railway lines often gained a second life as cycling or walking trails, both for domestic use and for tourism. The German Ruhr area, for example, markets its extensive network of cycling routes on abandoned (industrial) railway lines.

In Africa and Asia, differently from Europe and North America, the railway network kept growing until the end of the 20th century (Jedwab and Moradi, 2016; Jedwab et al., 2017; Okoye et al., 2019). The temporal trends and the role played by railway to sustain economic development was, as should not be surprisingly, ultimately different depending on the position of a given country on the (political and socio-economic) world map.

The most important technical innovation of the 20th century was the transition from steam engines to diesel and electricity. From a management point of view, the role played by the state increased enormously. The latter went hand in hand with the creation of the welfare state, and indeed the provision of *public* transport was often considered as a standard task for governments. Switzerland opted for nationalization of its railways in 1902, Italy in 1905, Japan in the following year, and Belgium in 1913. France and Great Britain, in, respectively, 1937 and 1946.

At the end of the 20th century the role of governments as the dominant players in the railway sector was brought into question again (Fremdling and Knieps, 1993). Great Britain, under Prime Minister Margaret Thatcher, took the lead and reintroduced competition between privatized companies in the exploitation of railways. Other countries switched to mixed systems, with The Netherlands, for example, allowing regional monopolies to commercial companies on (peripheral) parts of the network.

A Resurrection of Rail Transport?

In the last decades of the 20th century railways started to gain momentum again on both ends of the continuum of spatial scales. Globalization, in the first place, created an impetus for the construction of an integrated international network of high-speed railway lines. Japan was first with its famous Shinkansen (bullet) trains in 1964. From the 1970s high-speed trains began to be developed in Europe as well. France was the forerunner with its *Train à Grande Vitesse*. Germany followed with the InterCity Express, and Italy with the *Pendolino*. Also in Germany, Siemens developed and tested a Maglev (train with magnetic levitation), but this did not lead to large-scale adoption of the system. Another development on the global scale is intermodal transport, mainly with containers. Railway companies have secured some position in the ship-road-rail operational and management integration.

On the local level, urban tramways are making something of a comeback. A considerable number of cities all over the world have (re)introduced trams not merely to solve traffic congestion problems, but also to create an appealing atmosphere for the creative classes that is seen as the backbone of the current urban economy. A telling example is the reintroduction in 2018 of the tramway (or streetcar) in Detroit, the Motor City and the very symbol of the era of the automobile.

Railways and Economic Development: A Review of the Literature

History represents an important factor conditioning railways and more generally transport systems. About 70% of the railway lines operating today in Europe already existed in 1900 (Martí-Henneberg, 2013). A vast literature by economists, economic historians, geographers, and scholars of related fields includes various attempts to measure or quantify the impact of railway diffusion on various socioeconomic outcomes. Indeed, with the development of railways for the first time transportation costs over land were competitive to those over water.

In their seminal publications of the mid-1960s, Fogel (1962, 1964) and Fishlow (1965) introduced the *Social saving* (SS) methodology. It relates to the aggregate cost saving that the new technology (railway) allows in comparison with the next best alternative. SS represents a possible measure of the benefit to society of technological improvements. Omitting here some technical yet important details (such as the elasticity of the demand curve and the consumer surplus dear to economists), if P_{water} represents the price of quantity transported by water and P_{rails} the price of quantity transported by rail, and Q_{rails} the quantity (freight or passenger) transported by rail, then SSR (SS of Railways) can be defined, as $SSR = (P_{\text{water}} - P_{\text{rails}}) \times Q_{\text{rails}}$. SSR was considered by Fogel mostly as an upper bound of the gains induced by railways. The contributions by Fogel and Fishlow stimulated a vast new literature labeled cliometrics (for a review of the debate see O'Brien, 1977; Fogel, 1979; Leunig, 2010; Atack, 2019; Bogart, 2019).

Railway developments in the 19th century have been also analyzed in the more general context of rising international capital movements during the age of first globalization (1870–1914). The basic idea is that when in a given country net imports of capital from abroad were abundant (scanty), public investments on the construction sectors, including the railways, were relatively high (scanty) (Fenoaltea, 1988, Roth and Dinshob, 2008). Hence new construction is inherently of a cyclical nature. Various scholars have analyzed the backward linkages of railway construction and maintenance: the induced demand for manufacturing (metalmaking and engineering) and in particular of rolling stock (locomotives, freight and passenger cars; see for instance Ciccarelli and Fenoaltea, 2012). Backward linkages often had a limited, often local, spatial context. The development and diffusion of electricity as a source of power since the late 19th century induced a gradual replacement of steam locomotives with electric locomotives, as the average life-span of a steam locomotive was of about 40–50 years (Ciccarelli and Nuvolari, 2015) and consequently a new round of backward linkage effects.

In more recent decades, scholars have begun to focus on the spatiality of the impact of the railway, with analysis carried out at the regional level. This literature takes advantage of new developments in geographic information systems (Atack, 2013). This proved to be a powerful tool for displaying spatial phenomena, and to analyze the geographical diffusion of railways and its possible socioeconomic impacts, often at a much lower level of geographical aggregation than before (municipalities or parishes). The building of a geodatabase is often based on both historical sources and maps (for instance, the Library and Archive section of the website of the Italian Fondazione FS—<http://www.fondazionefs.it/content/fondazionefs/en.html>, last accessed December 2019—provides a rich set of digitized historical sources). The railway sector is generally well documented, as it was often regulated by public authorities, typically producing annual reports to Parliament. Information on the exact day of opening and length of each track, as well as the locations of stations and stops are often available. Historical maps represent another precious ingredient in the production of geodatabases, especially so when they are homogenous over time (Ciccarelli and Groote, 2017, 2018). Retrospective maps were often published in the occasion of international meetings such as the various International Exhibitions of the 19th century.

In most (western) countries the early diffusion of railway occurred in concomitance with the early phases of the first demographic transition. This is the a secular process of the shift from a preindustrial demographic system characterized by high and fluctuating birth and death rates to a modern regime of low and more stable death rates (first) and birth rates (later). As a result, the population was young and expanding rapidly during the first phases of railway construction. The concurrence between rapid railway diffusion and population growth stimulated various contributions attempting to identify a possible causal relation between them. Indeed, railway development might both follow and induce population and economic growth. Reverse causality is also possible representing a threat to the identification of causal relations (the endogeneity problem, to use economists' jargon). Emblematic of this approach is Atack et al., 2010 "Did railroads induce or follow economic growth? Urbanization and population growth in the American midwest, 1850-1860." It stimulated various contributions concerning different countries (among others, Gregory and Henneberg, 2010 for England and Wales; Groote et al., 2009 for The Netherlands; Berger and Enlfo, 2017 for Sweden).

The remaining of the chapter illustrates the geographical and temporal distribution of railway at the global and continental level, and for selected countries (Figs. 1–9). Tables 1–6 quantify the diffusion of railway during the "golden age" of the late 19th century.

Introduction

Railways as a system began with the introduction of the steam-powered locomotive in the early 19th century and the opening of the first public intercity railway: the Liverpool and Manchester Railway in the United Kingdom in 1830. This was the first guided transport mode that combined steel rails/steel wheels, steam engine locomotives, and a convoy. It was also the first mode of transport to be fully timetabled. Similarly, in many other countries, contemporary railways were built during the 19th century and, in specific contexts, were associated mainly with the development of different economic situations.

Surprisingly, the geography of railways systems has not been extensively investigated. In several countries, railways are part of the landscape, so scholars generally have not questioned their presence. In other countries, there are no railways anymore or only some residual rail operations, which are not considered.

In this context, the chapter presents the current overall geography of rail transport and offers an in-depth examination of the different factors that influence the construction, operation, and/or maintenance of railway systems around the world. The chapter is organized as follows: section “The Overall Geography of Rail Transport” analyzes the current situation of railway systems and their development, considering both infrastructure and use-related variables; section “Rail Geography as a Production of Multiple Factors” discusses the main factors affecting the development of railway systems; and last section concludes the chapter.

The Overall Geography of Rail Transport

While railways are commonplace in many countries worldwide, their geography varies significantly in terms of network length, density, and utilization (traffic intensity and passengers versus freight markets). In an attempt to introduce overall railway geography, country-level statistics supplied by the International Union of Railways (UIC) have been considered to build a typology of railways systems. Four main variables have been considered: the density of rail lines (DensityLines) and the density of high-speed lines (at least 250 kph) both in km/km² (DensityHSL); passengers’ traffic (Pkm_km) and freight traffic (Tkm_km), both in relation to the total length of rail lines.

This led to six main groups (Fig. 1):

- Medium-sized countries with a high density of rail lines (cluster 1)*: In this group, mainly countries in Eastern Europe and the United Kingdom are included. The density of railways is the highest of the sample and traffic per kilometer is limited, slightly over the median value (see Fig. 1: boxplot analysis).
- Medium-sized countries with both conventional and high-speed lines (clusters 2 and 3)*: These two clusters encompass most of the countries in Western Europe and South Korea (cluster 2), in addition to Japan and Taiwan (cluster 3), where the highest density of high-speed rail networks can be found. The main difference is that those countries in cluster 3 present high population densities along major rail corridors, and the use of railways is more consolidated, which implies a higher Pkm_km value.
- Large or very large countries with high freight traffic (clusters 4 and 5)*: In this case, due to the large size of the countries included in this group, the density of rail lines is very low compared to the above-mentioned countries. Of course, this does not prevent dense railways networks in densely populated areas, like Eastern China (see below). However, this group is characterized by high volumes of freight

Figure 1 Classification of the world's countries: clustering and boxplot analysis (based on using the *k*-means clustering technique and data from UIC 2016 as a compromise between actualized data and the sample size).

traffic (in relation to their length of rail networks). The main difference between clusters 4 and 5 is passenger traffic, which is much higher in cluster 4 (namely, Russia, China, and India) and follows similar patterns to those found in clusters 2 and 3.

- d. *Large countries with reduced railway use (cluster 6)*: In this group, countries present a very low density of rail infrastructure (even nonexistent in some cases) and reduced use of the railway system, both for passengers and freight.

In addition to the overall geography of the world's countries, close attention must be paid to the current situation of high-speed rail systems (Fig. 2):

Currently, there are 13 countries with high-speed rail infrastructure for speeds over 250 km/h (mostly included in clusters 2 and 3). In this sense, China is the world's leader in HSR extension (21,782 km length), followed by Japan (2848 km), France (2734 km), and Spain (2482 km). However, the situation concerning the density of lines (*DensityHSL* variable) is quite different: while Japan,

Figure 2 World's countries with high-speed rail infrastructure (at least 250 km/h) in 2018. *Source: UIC.*

Figure 3 The impact of spatial unit on indicators: high-speed lines in Spain (at least 250 km/h). *Sources: Data from ADIF (Spanish Infrastructure Administrator) and FFE (Spanish Railway Foundation), 2019.*

South Korea, and Taiwan present the highest density values of this kind of infrastructure (over 7.327×10^{-3} km/km²), China, Turkey, Austria, The Netherlands, and the United Kingdom have less than 2.641×10^{-3} km/km².

Of course, any analysis of the geography of rail systems depends on spatial units. This chapter is not the place to elaborate on the so-called Modifiable Areal Unit Problem (MAUP) (Arbia, 1989). But for sure, the picture one gets changes dramatically, subject to spatial units, in line with urbanization patterns that are better rendered at subnational level (Fig. 3).

It is also worth noting that in countries with more than one single rail line, traffic density can be quite diverse within a single network. In France, typically, the lowest-density lines account for 46% of network length but only 6% of the supply. Conversely, 78% of the supply is concentrated in only 30% of the network (Table 1).

Rail Geography as a Production of Multiple Factors

The geography of rail transport unveiled in the previous section obviously does not fall from the sky. It is the product of numerous factors that are discussed below, with a special emphasis on rail networks.

Geo-Economic Factors Versus Economic History

It would be tempting at first to expect that countries' demographic weight and surface would favor the development of railways, notwithstanding internal heterogeneity. However, developing and operating railways is expensive. All other things being equal, economic development is thus also a key factor. Economic development would directly increase passenger and freight demand and would suggest that public authorities or private interests would have enough means to build the infrastructure.

Table 1 Network vs. supply concentration in France

Line group	Length	Supply
Main lines (UIC 1-4 and HSLs)	30% (8900 km)	78%
Intermediate lines (UIC 5-6)	24% (7000 km)	16%
Thin lines (UIC 7-8)	46% (13,600 km)	6%

Supply is given in gross ton-kilometers hauled (GTKM).

Source: Rivier and Putallaz (2005).

Table 2 Regression models for Ln railway length at the country level ($n = 82$)

	Model I	Model II	Model III
Intercept	-2.034*	-6.570***	-6.762***
Ln POPULATION	0.617***	0.689***	0.401***
Ln GDP/CAPITA		0.707***	0.768***
Ln AREA			0.379***
Adjusted R ²	0.498	0.692	0.794

Significant at *** 99%, ** 95% or * 90% level of confidence

For the subset of 82 countries considered above, we set up a multiple regression model where the length of railways is a function of population, area, and GDP/capita. Following the logarithmic transformation of all variables, the parameter estimates should be interpreted as elasticities. The first factor is population (proxy for market size); then comes GDP/capita. Once controlling also by surface area, railway length has the highest elasticity with GDP/capita (a 1% increase in GDP/capita would increase railway length by 0.77%, all other things being equal) (Table 2).

However, such a multiple regression does not really make sense. Indeed, it is worth noting that many of today's rail lines were actually built a long time ago and would arguably not be built from scratch today, given the development of other transport modes in the intervening time.

Following Kondratiev's theory, the economy experiences long-term waves. Although this theory has been challenged, each cycle involves major innovations that will drive the next period of high growth (A phase). The second wave, more or less in the second part of the 19th century, was based largely on railways, which were both a major innovation and a main industrial activity and were intensively utilized by the then heavy industries. As a result, countries that took part in the industrial revolution at this time were very quickly covered by a high grid of railways, of which many are still operated today (Martí-Henneberg, 2013). A typical example is Belgium (Fig. 4). The network has been built mostly over the second Kondratiev wave, then consolidated over the third wave, and significantly dismantled during the fourth wave, when car ownership and motorways became standard. This process was only balanced by the opening of some high-speed and freight lines over the past 25 years. Given the cost of maintaining and operating railways and intermodal competition (see below), it is likely many existing lines would not still exist if they had to be built today from scratch.

In another context, many railways in Africa were designed by the colonizer. British explorer Stanley, who was recruited by King Léopold II of Belgium to explore and acquire lands in Congo, stated that "without the railroad, the Congo is not worth a penny" (Deckard, 2019: 246). Railways were essential to overcome non-navigable parts of the Congo River. More generally, colonizers in Africa built railways to control lands and to transfer huge amounts of minerals and agricultural resources to metropolitan areas. This ensured penetration lines with low density and scarce interconnections (Taaffe et al., 1963), often until today (Oliete Josa and Magrinyà, 2018). Several lines have ended (even though they are still part of local landscapes), but surviving lines mostly date back to colonial times.

During the 20th century, especially in the second half, the evolution of railways was oriented mainly toward high-speed rail systems. The first high-speed line was the Tokaido Shinkansen line, built in 1964 between Tokyo and Osaka in Japan. Since then, high-speed lines have been developed in many other countries, mainly in Western European and Asian countries. High-speed lines (HSL) were designed initially as a transport alternative to intermetropolitan connections, which were working close to maximum capacity and facing growing traffic demand (Vickerman, 2009). Therefore, in the beginning they were oriented to discharge conventional lines servicing the main corridors in different countries. However, it quickly appeared that HSR could compete with airlines mainly for business purposes, securing higher market shares and contributing to a decrease in their absolute level of use (see Dobruszkes et al., 2017, for a review). In recent decades, the development of high-speed rail systems, transitioning from single lines to a complex mode of transportation, and their coexistence with conventional railways, require a global analysis to understand the different factors affecting the evolution of this transport system.

Figure 4 Belgium's railway over time.

Physical Geography

Anyone who would like to develop a railway would first face the constraint of physical geography. Major adverse constraints are water and relief. Rivers, lakes, and seas impose bridges or tunnels, which can only increase the cost of new infrastructure, as well as maintenance costs. Of course, bridges spanning seas and undersea tunnels are limited in length. In 2019, the tunnel with the longest underseabed section was the Channel Tunnel between France and England (37.9 km, out of 50.5 km). In northern Japan, the Seikan Tunnel is 53.9 km, of which 23.3 km are under the seabed. Beyond these extreme figures, it is much more common for over- or undersea rail tunnels to range from a few hundred meters to a few kilometers. There are actually more long bridges over the water than long tunnels. The longest bridge is currently the Danyang–Kunshan Grand Bridge (164.8 km long in total, with a 9 km section across the open waters of the Yangcheng Lake in Suzhou). The bridge opened in 2010 as part of the Beijing–Shanghai high-speed line. While long undersea tunnels are recent, long bridges over the water date back to the 19th century. For instance, the 9.3-km Norfolk Southern Lake Pontchartrain Bridge in the United States was opened in 1884.

Relief is not friendlier to railways. “Heavy” rolling stocks can only face gentle slopes, about 1% (or 2.5%, which is the recommended maximal high-speed rail slope). Lighter rail systems accept higher slopes (with a slope of 7.9%, Zurich’s S-Bahn 10 to Uetliberg is reported to be a record in Europe), but this may restrict operations, especially speed. Rack systems may help to overcome relief, but in most cases relief is overcome by bridges over valleys and tunnels inside mountains. Rail tunnels through mountains were first established during the late 19th century, and at rather high altitudes to make them shorter. For instance, the first Alpine rail tunnel, the Gotthard Tunnel, which opened in 1882, was already 15 km long. Its highest point is 1151 m. In addition to high construction costs, its altitude involves rather inefficient access and egress ways, with curves (if not serpentes) and bridges to maintain acceptable slopes. Length has been limited by technology and the use of steam engines, which were difficult to manage in urban underground systems (Dennis, 2013). More recently, some countries have engaged in building so-called base tunnels. In short, these flat tunnels are built at much lower altitudes, but are thus much longer and more expensive. The new Gotthard base tunnel is 57 km and is currently the longest and deepest tunnel in the world. Its highest point is some 602 m below the older tunnel’s one. Its cost was estimated at CHF 9.56 billion in late 2015 (€8.75 billion euros at that time).

Soils may also make the building of railways more complex. In Scotland (UK), for instance, the construction of the West Highland Line had to confront the problem of peat bogs, which eventually involved the application of specific techniques (Le Vay, 2009).

All this significantly increases the cost of developing railways. In the first instance, the rationale for building railways, despite adverse physical geography, would be balanced by the wealth of countries (public authorities and/or private investors), potential market size, and modal alternatives, which can all change over time. An alternative is to avoid or skirt around obstacles at the cost of detours of all scales. Some stakeholders have proposed restricting HSLs to single-track lines in case of very high infrastructure costs and moderate traffic (Castillo et al., 2015).

Figure 5 The impact of an urban system on a high-speed rail network.

Urban Systems

The previous modeling exercise, although apparently successful, does not reveal the subtle impact of urbanization patterns on the geography of rail systems. For instance, China is a large country by surface and population, and its GDP per capita is close to the world's average. But its rail network is apparently less developed than expected because the Chinese population is highly concentrated. In other words, a large part of China is not heavily populated, so railways are scarce in these areas. Actually, the geography of railways could be better understood under the framework of urban systems. An urban system is a combination of city size and the intensity of interaction between them. All other things being equal, this significantly shapes the need for travel, and thus the geography of flows and possibly the rationale for railways. For instance, the national urban system's shape has affected the design of high-speed lines in recent decades. **Fig. 5** clearly shows that in a country where one city dominates the urban system (typically Paris in France and, to a lesser extent, Madrid in Spain), the HSR would be star-shaped. At best, radial lines would be interconnected through the city center (Madrid) or its suburb (Paris), but they are built primarily to link the dominant city to other cities. In contrast, a polycentric urban system would spread the demand across more links, which calls for more rail lines, although it may also make them less economically or even socially profitable, given the cost of the infrastructure. Germany is a typical case here. A much easier case is when the urban system is mostly linear, as in Japan or Italy. In such cases, one single, high-speed line makes it possible to serve a significant share of the national population. In extreme cases, however, the demand along this axis may become so large that a second line is needed. This is the case in Japan, where traffic forecasts had the effect of justifying the construction of the Chūō Shinkansen maglev line between Tokyo and Osaka (which is expected to be partially opened in 2027).

Obviously, the shape of urban systems not only influences the spatial patterns of infrastructures, but also services and passenger flows. The territorial situations of HSR cities (Ureña et al., 2012) in relation to other cities in the network suggested the implementation of different kinds of services adapted to each connection's needs. For instance, in Spain, the existence of regional HSR services between large metropolitan areas and close smaller cities is the cause/consequence of interactions between cities, mainly related to labor markets (in many cases fostered by the new infrastructure itself); or even new low-cost HSR services are oriented to cover the increasing demand for leisure mobility.

Distances, Travel Times, and Intermodal Competition

In addition to urban systems (and linked to them), the geography of railway lines and their use is also affected by distances—and thus travel time—between places and related intermodal competition. Once travel time/distance becomes too long, airlines start to gain market share. Considering 161 city-pairs across Europe, Dobruszkes et al. (2014) found the ability of HSR to compete with airlines decreases significantly between 2.0 and 2.5-h of HSR travel time. Conversely, the Brussels case shows that rail use to commute to Brussels increases with distance. Commuters who live in close suburbs underuse trains, usually because the service is poor, but likely also because of lifestyles connected to social attributes (Strale, 2019). Of course, the terms of competition between railways, road transport, and air travel also depend on factors other than travel time (Zhang et al., 2019). At a time when medium- and long-distance accessibility is considered a key element of the attractiveness of cities and regions, intermodal competition goes beyond infrastructure and travel times to also consider services (routes, frequencies, and timetables) (Moyano and Dobruszkes, 2017; Moyano et al., 2018). In addition, potential travelers' income vs. fares is key. There are countries in which trains have remained a transportation mode for the masses. In other cases, especially in the case of HSR, premium fares apply. All other things being equal, this favors competition from other transportation modes.

Railway development and operations have become increasingly challenged by the rapid expansion of air services and decreasing airfares. In many areas, airlines have opened multiple new routes, which increases pressure on railways. Competition is direct (for those passengers whose destination is fixed). But it is also indirect as cheap flying options can divert passengers from trains because they offer new destination options. For instance, a cheap flight from London to Lisbon may divert passengers from British resorts. Especially in Europe, lots of long-distance rail services, both domestic and international, and both daytime and overnight, have disappeared. International rail services from Brussels (**Fig. 6**) are a typical example. At best, some of them have become HSR services. Note that the advent of HSR may also have created links that did not exist before, typically to London via Lille. Precisely, in contrast

Figure 6 Changes in international services from Brussels.

with air transportation, where the flexibility to fit supply and demand is higher because connections are city-to-city, HSR runs through the territory and potentially generates impacts on the in-between regions. This implies that, in time, HSR acquired a social and political compromise for servicing smaller intermediate cities (Moyano and Coronado, 2018), guaranteeing that smaller communities would remain accessible and (or) that their long-distance accessibility would improve.

It is worth noting, however, that the terms of competition can change over time. Today's domination of many markets by air travel could later be challenged in the event of a sharp increase in energy costs or if the implementation of strong regulation forced passengers to reconsider trains in the name of environmental issues (Dobruszkes et al., 2017).

Railway Logics

The current shape of railways is also influenced by the essentials of this transport infrastructure itself. Many of the existing lines are the consequence of different steps of the development process: the railway system was not built in one go but is the result of consecutive expansions. Therefore, preexisting lines condition future corridors and branches. In the case of HSR, the logics of infrastructure growth are strongly related to preexisting conditions, mainly because the costs of construction are expensive. For instance, in Spain, the new connection to Granada takes advantage of the existing line between Madrid and Málaga (which is still below its capacity of exploitation), and only an HSR branch from Antequera is newly built. For sure, if the Andalusian corridor did not exist, the connection between Madrid and Granada would be different.

Political Factors

All the previous factors can be considered natural constraints and market forces, which likely prevailed in earlier times, when private investors took the risk of developing railways and rail travel was nearly the only efficient option. But times have changed. In many countries, the development and maintenance of railways are largely (if not exclusively) funded by public authorities, which also compensate companies for the lack of financial profitability of many services. Public authorities have many rationales for funding railways; these range from social goals (favoring the masses' right to mobility) to environmental concerns (rail operations are "greener" than other transportation modes if traffic is dense enough) to economical concerns (e.g., supporting one's national seaport against competitors) to land planning considerations (e.g., serving remote areas and increasing national or international integration). But of course, the one who pays also decides. As a result, the rationality of natural constraints and market forces is then partially replaced by political considerations. Obviously, in a democracy, governments have the power to fund facilities or services to achieve various goals, whatever the views of many transportation experts, especially liberal economists. In one sense, economical rationality is partially replaced by political rationalities. Of course, the border between dreams and the actual impact of such

Figure 7 Potential itineraries for the Northern European HSR Source: Adapted from Moyano and Dobruszkes (2017), after SNCF (1998).

investments is somewhat unclear. It is thus not surprising that economists have largely opposed investments they deem socially unprofitable (see Albalade and Bel, 2012).

In the meantime, there are many examples of public authorities diverging from market forces, for the best and the worst. For instance, Spain first built an HSL between Madrid and Seville in anticipation of the 1992 Universal Exposition of Seville. The authorities argued that the less-developed south needed to be boosted. As a result, the Madrid-Barcelona HSL, which links Spain's two largest cities by any metric, was opened more than a decade later. There's no need to be an expert in spatial economics to understand that the largest market (and higher potential for the modal shift from planes) was between Madrid and Barcelona. Germany is also an interesting case. As long as the country was divided, HSLs were developed only within Western Germany, following a north-south logic. Then, in 1989, the Berlin Wall fell and Eastern Germany's communist regime collapsed in the aftermath. Germany was reunified in 1990, with Berlin (located in the middle of former Eastern Germany) as the capital. As a result, it became necessary to link Berlin with the western cities by HSR, so the priority became the construction of an east-west HSL, which opened in 1998.

The weight of political factors can play out at various levels. For instance, once it has been decided to link two main cities by HSR, the public authorities have to agree on an itinerary. The choice is often a mix of all the factors highlighted in this section. But because HSR has become an appealing facility that is supposed to boost the economy (Delaplace, 2017; Vickerman, 2018; Zhang et al., 2019), influential elected persons located en route would want to secure some services too and thus influence the HSL's shape (Moyano and Dobruszkes, 2017). Fig. 7 clarifies this in the case of the so-called Northern European HSR, designed primarily to connect Paris to the Channel Tunnel but also to Lille, Brussels, and beyond (Amsterdam and Cologne). Without any cost constraints, a triangle going straight from Paris to the Channel Tunnel and to Brussels may have been considered. But this would have maximized the length of the HSL, and thus the cost. Furthermore, Lille, which is one of the largest of France's cities, would have been bypassed. Various HSL designs via Lille were analyzed (Fig. 7). The final compromise mixes attractive travel times between the main cities and reasonable costs, on the one hand (market force), and Lille's location in a central position, if not an HSR hub, on the other hand (notwithstanding the real services that would later serve the city, see Moyano and Dobruszkes, 2017).

The Northern European HSR was partly justified by its contribution to European integration. But railways are like the Janus face, and they can also serve much darker designs. Existing railways were intensively used by the Nazis to send people to concentration and extermination camps. And under the Apartheid regime in South Africa, railways were a concrete tool the government used to manage spatial-racial

segregation (Baffi, 2014; Pirie, 1987). Non-white persons were forced to live in townships. Such suburban townships were either built along railways, or suburban railways were built to serve townships. The result of this design was a deliberate separation of nonwhite and white residents that still allowed for the exploitation of the segregated workforce via suburban line transport. In contrast to Jefferson's idea of "civilizing rails," Pirie (1982) was right to conclude that "decivilizing rails" existed in Southern Africa.

Conclusions

This chapter presents an overall geography of railways worldwide, identifying a typology of countries, which depends on the characteristics of their national rail systems, and evaluating the main factors affecting the spatial patterns of both rail infrastructures and traffic. These main factors are related to natural/physical constraints, market forces, and political interests and, although they are discussed separately in this chapter, all of them are interconnected: some factors influence others in one way or another. In addition, not only railways are influenced by the presented factors; transport systems can also reinforce or even create certain logics: for instance, while urban systems condition railway infrastructure and services, a good railway connection can influence inter-urban relationships (a new HSR connection with regional services can foster new mobility patterns). In this sense, this chapter exposes the relevance of these factors in the development of railways, and how their importance and relationship have been changing depending on the context (geographical, economic, political, etc.) during decades of evolution.

Acknowledgment

We would like to thank the Paris-based UIC team for letting us access the data utilized in Section 2.

Biography

Frédéric Dobruszkes holds a PhD in geography (2007) from the Free University of Brussels (ULB). He is currently an FNRS research associate and lecturer at the same institution. His main research interests are transport geography (especially long-distance mobilities, urban transport, and social conflicts around aircraft noise) and transport policy, including the design of public transport networks and accessibility issues faced by persons with reduced mobility.

Amparo Moyano holds a PhD in civil engineering (2018) from the University of Castilla La Mancha (UCLM), Spain. She is currently an assistant professor and researcher in the School of Civil Engineering of the same. Her main lines of research relate to transport and urban planning, especially focused on (1) territorial effects of high-speed rail systems and their influence on mobility patterns and (2) urban mobility and accessibility analysis using new data sources (Big Data), mainly oriented to the integration of rail stations into urban structure and local transport systems.

Introduction

Transport infrastructure networks are the main structuring element in a territory. In order to serve as such, it is of prime importance to guarantee access to the network, which varies with each transport mode. Rail, maritime, and air transport networks have only discontinuous access through their nodes, in the form of stations. This creates a special relation with the territory, known as the tunnel effect: only stations allow entry to and exit from that “tunnel.” Although railway lines run along a territorial corridor, accessibility is only possible through stations, which become the access nodes. All the connections with the surrounding territories are fully dependent on the station location and its access by other modes: walking, cycling, public transport, or private car. Most are dependent on the road/street network that serves the rail node.

Rail transport should therefore be studied on two different territorial scales:

1. macroscale: connection with other stations (nodes in the rail network); travel time, frequency of services, etc.
2. microscale: potential accessibility of people and activities to/from stations; access and egress times, modes, congestion, reliability, etc.

Rail issues are most important at the macroscale. Rail networks are usually planned at national or international strategic levels, and must take into account a large number of territorial scale issues in regard to rail network planning, such as the location of the main origin/destination points and distances versus travel time through the rail network.

The scope of the following sections focuses on long and medium distance rail transport, as urban rail transport is covered in the urban transport section of this Encyclopedia, such as in 10610 Light Rail. Other relevant and interrelated readings in this Encyclopedia are 10693 High Speed Rail, 10635 Planning for Rail Transport, and 10462 The geography of rail transport.

• Stages in a rail trip

In long and medium distance travel, a trip using the rail mode can in most cases be disaggregated into at least three stages, as shown in Fig. 1: T1 (the first-mile trip) includes the connecting trip from the origin (i) to the nearest train station (A_i , entry station), T2 includes the trip on the rail service, and T3 (the last-mile trip) includes the final trip from the arrival train station (B_j) to the final destination (j).

The rail station thus acts as an intermediate—transfer—node, which is not highly attractive in itself as a final destination, but where some utility is obtained. Hence, accessibility to the nearest railway station via the local network plays an important role as a provider of “connectivity” to the long-distance network.

Railway lines therefore produce territorial impacts that are relevant for regional and local development and cohesion policies, and which must be measured to design adequate investment and management policies as part of a fully integrated intermodal vision.

This chapter is organized as follows: after Introduction, Territorial Effects of Rail Transport Section includes an overview of the main territorial impacts of rail transport, focusing on describing accessibility indicators as a valuable tool to assess these impacts. Then, Territorial Equity Effects Section discusses on territorial equity effects and measures them in the case study of the Spanish HSR network development. A micro-level analysis is then included in Microlevel Analysis: First/Last-Mile Links Section, where territorial impacts present in first/last mile links are also assessed through a case study; in this case a HSR corridor. The chapter ends with a “Summary and Conclusions” section.

Territorial Effects of Rail Transport

The territorial policy of the European Union has established a specific action on territorial cohesion with the goal of promoting a more cohesive and balanced territory, seeking greater socio-economic equity and reinforcing territorial cooperation (EC, 2008). One

Figure 1 Travel stages including access, rail service, and egress connection to destination.

aim of the EU cohesion policy is to provide better connectivity through the so-called TEN-T (Trans-European Networks-Transport), with the additional purpose of fostering competitiveness and employment. At the core of this cohesion policy is the development of an EU-wide rail network.

However, new rail transport developments may induce spatially polarizing impacts, a phenomenon that could apply to any territory in any region. There are ad hoc methodologies to assess these impacts, such as those designed to measure changes in the spatial distribution of accessibility caused by transport infrastructure networks, and high-speed rail (HSR) lines in particular. These methods generally target strategic international or national macro levels (Banister and Berechman, 2003; López et al., 2008) and require the calculation of accessibility indicators—mainly using Geographical Information Systems (GIS)—to analyze changes in accessibility levels impacted by new rail lines (Bröcker et al., 2010).

The impacts of the territorial accessibility provided by rail networks are not limited to locations in the immediate vicinity of railway stations, and this effect is even more significant in the case of HSR networks. Travel patterns in cities outside rail corridors may also change in response to the new services (Garmendia et al., 2012). For these cities, the nearest station functions as an interchange node to connect to the whole rail network, so cities located outside the rail corridor may also obtain accessibility benefits. These territorial impacts are known as “spillover effects” (Gutiérrez et al., 2010). Cities with railway stations became core locations for access to the rail network, and thus gain accessibility to the whole region/country (Monzón et al., 2013).

- **Accessibility indicators to measure the territorial impacts of rail transport**

The analysis of how rail networks influence the territorial distribution of quality of access to desired destinations is usually supported by calculating accessibility indicators. From a spatial perspective, accessibility is a feature of a given location, related to the ease with which “desired” destinations can be reached from it. There are many formulations for measuring the accessibility provided by transport networks, all of which seek to provide an output to different study targets. An extensive review of accessibility indicators and their applications in different territorial contexts can be found in Geurs et al. (2012).

The accessibility enabled by rail networks is usually studied at national or international macro strategic planning levels. This broader scope means that accessibility indicators must be calculated taking data availability restrictions into account (basically detailed travel and mobility data), and the affordability of the corresponding computation efforts. On this coarser scale, travel times are calculated using long-distance transport networks, and major urban agglomerations are usually selected as “desired” destinations. One general formulation of an accessibility indicator for measuring macro rail territorial impacts is the “potential accessibility indicator” (Monzón et al., 2019) shown in Eq. (1):

$$PA_i = \sum_j \frac{P_j}{I_{ij}} \quad (1)$$

PA_i is the potential accessibility for each origin i to all destinations j . P_j is a variable that measures the activity level of each destination (population/GDP), and I_{ij} is the generalized travel time/cost from i to j . The formulation for the travel time is as follows (Eq. (2)):

$$I_{ij} = t_{\text{road}}(i, S_i) + t_{\text{rail}}(S_i, S_j) + t_{\text{road}}(S_j, j) + \theta_{\text{rail}} \quad (2)$$

where $t_{\text{road}}(i, S_i)$ is the access time by road (default mode) from the trip origin to the nearest station; $t_{\text{rail}}(S_i, S_j)$ is the travel time using the railway network to the station nearest the destination, and $t_{\text{road}}(S_j, j)$ is the egress time by road from this station to the destination itself. It also considers a set of penalties (θ_{rail}): frequency of service, railway line change, road to railway mode change.

The PA_i value is a measure of the absolute rail accessibility of location i , and can be used to measure the impacts of new lines or improvements in existing ones by measuring the change in the accessibility values between two horizon years. The difference in accessibility is calculated as a percentage of the change in potential accessibility. The changes between two consecutive horizon years are as follows (Eq. (3)):

$$PAC_i^{H_x-H_y} = \frac{PA_i^{H_x} - PA_i^{H_y}}{PA_i^{H_x}} \times 100 \quad (3)$$

$PAC_i^{H_x-H_y}$ is the change in the values of the potential accessibility indicator between two horizon years H_x and H_{x+1} .

Figure 2 Absolute potential accessibility (PA) due to the rail network in the horizon years 1990 and 2015 (before and after the development of the HSR network).

A positive PAC_i value indicates an increase in accessibility in year H_y compared to year H_x . The higher PAC_i values therefore mean greater improvements in accessibility in a specific territory.

Territorial Equity Effects

The degree of territorial equity can be measured in terms of the spatial distribution of accessibility levels across a given territory. These spatial distributive effects are highly significant for the assessment of rail developments, as it is important to evaluate whether new rail corridors contribute to a more balanced distribution of accessibility. If the accessibility improvements are located in places that already have good accessibility levels, there is a risk of polarizing the territory: rich locations became richer and poor ones even poorer.

• Accessibility indicators to measure territorial equity effects

Once the differences in accessibility have been determined in the different periods of building the rail network, it is advisable to calculate whether these accessibility gains are equally distributed throughout the territory. The dispersion of accessibility values is a measure of accessibility-based territorial equity, which must be analyzed in conjunction with the overall increase in accessibility. It may be that greater accessibility for the country as a whole could be caused by very high increases in certain locations and much lower increases in others. The final result may exacerbate the differences between regions and lead to losses in territorial cohesion. This effect is measured by calculating the “potential accessibility dispersion” (PAD) index (Ortega et al., 2012) as formulated in Eq. (4):

$$PAD^{H_x} = \frac{\sigma^{H_x}}{\frac{\sum PA_i^{H_x} \cdot p_i^{H_x}}{\sum p_i^{H_x}}} \quad (4)$$

where PAD^{H_x} is the coefficient of variation in the horizon year H_x , and σ^{H_x} is the standard deviation of $PA_i^{H_x}$ values, weighted by the population $p_i^{H_x}$. High PAD values mean more polarized accessibility distributions, and less territorial cohesion. Finally, the change in territorial cohesion between horizon years can be measured by the territorial cohesion index (TC), as expressed in Eq. 5:

$$TC^{H_x-H_y} = \frac{PAD^{H_x} - PAD^{H_y}}{PAD^{H_x}} \times 100 \quad (5)$$

where TC is the change in territorial cohesion between two horizon years: H_x and H_{x+1} . A positive TC value represents an increase in territorial cohesion between the two horizon years. This value can be normalized by assigning a value of 1 to the average PA value. Once the values are mapped, they reveal which cities have higher relative accessibility values, and whether the improvements are uniformly distributed (approximate average values) between two horizon years.

• Case study: Territorial effects of 25 years of Spanish HSR network development (1990–2015)

Let us now analyze how to apply the indicators defined above to measure territorial impacts and equity. They have been used to assess the impacts of developments in the Spanish HSR network in the period between 1990 and 2015 (Monzón et al., 2019). It is currently the second longest HSR network in the world, with over 3000 km. This major network development has significantly improved rail accessibility in absolute values (PA) in the country, along with a wholesale transformation of the spatial distribution of rail accessibility values (PAC). For this analysis, the potential accessibility formulation was computed in GIS for each municipality (NUTS-5 level).

Figure 3 Potential accessibility changes (%) due to rail developments in Spain during 1990–2015.

Table 1 Accessibility values (in thousands) 1990–2015 and their changes (%)

Area/year	1990	2015	1990–2015
<i>Accessibility indicator</i>	<i>PA (000)</i>		<i>PAC (%)</i>
National average	128	190	48.6
Barcelona	210	263	25.5
Bilbao	117	134	14.5
Malaga	105	198	88.3
Madrid	282	393	39.3
Seville	123	215	74.5
Santander	90	128	47.2
Valladolid	122	236	93.9
<i>Territorial cohesion</i>	<i>PAD</i>		<i>TC index (%)</i>
National average	0.46	0.35	14.5

PA, potential accessibility; PAC, potential accessibility change; PAD, potential accessibility dispersion; TC, territorial cohesion.

The accessibility values for the PA indicator are shown in Fig. 2 for both the horizon year 1990, before the start of the HSR network, and for 2015. The figure on the right shows the values for the same indicator after the construction of some 3000 km of lines operating at commercial speeds between 250 and 350 km/h. Quantitatively, average accessibility values on the Spanish mainland have increased by 48.6% since 1990, although as these improvements are associated to the new HSR corridors, they are unevenly distributed.

The 2015 accessibility values are not only higher than in 1990, but also more balanced, with a 15% reduction in the dispersion of accessibility values: PAC (%). Fig. 3 shows a graphic representation of the percentage of change for each municipality in the 1990–2015 period.

Table 1 shows the evolution of accessibility for the whole country and for certain specific nodes. Cities with low PA values in 1990 such as Seville, Malaga and Valladolid—due to their travel time to the main centers of economic activity—received a significant impact when they became HSR stations on the new lines. Cities like Bilbao and Santander in the north of the country, where no new lines were built, received only spillover effects, which are much weaker. Large cities like Madrid and Barcelona are less dependent on their connection to other parts of the country so their accessibility improvements are not as high, even though they became nodal

Figure 4 Isochrones to access stations in the Madrid-Valencia HSR corridor (Spain).

stations on the new HSR network. The lower part of [Table 1](#) also shows the positive territorial cohesion: less dispersion of accessibility values (PAD), representing a net increase of 14.5% in the territorial cohesion index.

Micro-Level Analysis: First/Last-Mile Links

Many studies on accessibility and spatial equity issues have been done at micro/local levels, where “desired” destinations usually refer to urban facilities such as healthcare services, playgrounds, or urban parks. This requires transport planners to efficiently interconnect railway stations with secondary transport networks and local public transport in order to reduce access/egress travel times. This also highlights the importance of quality of access to the railway station, since “most of the travel time (and effort) is spent on getting to and from the station, and this constitutes the bulk of the journey travel time” ([Givoni and Banister, 2012](#), p. 306). It is, therefore, necessary to consider the entire integrated transportation chain—the door-to-door trip—in the study of rail services. Demand for rail services can be assumed to be higher if railway stations are situated in central locations that are well connected to rail and transit systems, and the issue of first/last-mile trips is indeed one of the current challenges facing rail services ([Lane, 2012](#)). As most rail accessibility studies have been done at the macro level, accessibility derived from first- and last-mile trips has been unevenly and scarcely researched. Investments in quality local transit services to stations can improve both access to and from stations and interconnections between short- and long-distance transport networks.

Another important issue to ensure access from local transport (including walking and cycling) is the location of stations. The best transportation solution is to locate stations in dense, centralized, and highly accessible locations ([Guirao and Campa, 2014](#)). However, in already developed metropolitan areas, land availability and building restraints make it difficult to locate new stations in central business districts (CBDs). Indeed, the type of access available may pose difficulties in car-oriented cities affected by sprawl, as may occur in many US cities according to [Lane \(2012\)](#).

- Case study: Measuring the spatial distribution of access times to a railway station

Accessibility indicators are frequently used to assess access to the nearest railway station. The accessibility indicator in this case is simply travel time from each municipality i to the nearest station in the Madrid-Valencia HSR corridor in Spain (Monzón et al., 2016). The minimum time path itinerary to access the HSR station is calculated for each municipality, making possible to graphically represent the isochrones of the territory served by each station. Isochrones are often taken as accessibility indicators as they are easy to understand and show the areas that can “reach” certain destinations within a given time threshold in graphic form. In Fig. 4, the destinations are the HSR stations in the corridor, and the time thresholds were 10, 20, 30, 45, 60, and 120 min. The use of isochrones helps identify the territories with higher accessibility needs in order to decide on the best solution to improve their situation.

Summary and Conclusion

In summary, this chapter has highlighted the importance of territorial equity effects of rail transport, focusing on the important role of accessibility indicators as supporting spatial analysis tools. In addition, evidence from two selected case studies is included, providing sound assessment methodologies based on the computation of accessibility indicators. These include the case of HSR on both macro- and micro-assessment levels.

It is therefore necessary, when planning rail lines, to approach territorial scale issues from two different perspectives: macro, considering the whole corridor/region; and micro, focusing on the location of the station and its connectivity through local public and private transport networks, that is, addressing first/last mile links.

Assessment at the macroscale should aim to identify solutions that ensure improvements in accessibility levels in the region/corridor that is directly affected by the new investments, as well as in nearby regions/corridors in order to achieve wider territorial spillover effects. This requires planning large-scale rail projects following strategic assessment frameworks that consider not only rail accessibility, but also connectivity with road and air networks. A comprehensive assessment of the territorial effects of rail projects at the macroscale is thus a challenge for transport planners. Accessibility indicators are widely applied to measure this kind of territorial effect and, together with GIS tools, to map their impacts. However, new or improved railway lines and services should seek to achieve a better distribution of accessibility to promote territorial equity. Rail networks have positive structural effects when improving cohesion among different locations within the region. Every town and city is entitled to accessibility potential in order to foster their development and ensure their access to services.

The lower scale consists of assuring accessibility to stations from the surrounding territory, implying actions in two dimensions: good station location and its access by local transport modes (Ureña et al., 2009). In principle, all local transport—public transport, private cars, and nonmotorized means—should facilitate access to railway stations, which requires a joint land-use transport strategy, city design, and supporting services for travelers in the vicinity of the stations. It is therefore necessary to implement a multimodal and LUTI (land use & transport interaction) approach to transform railway stations into core elements of the urban fabric (Monzón and Di Ciommo, 2016).

Introduction

Railway management differs from management of other technological or commercial activities. The present analysis focuses on the particularities of railway management in relation to the characteristics of the industry. Therefore, it unveils and discusses all the factors related to the internal and external environment of railways that are essential for an efficient management. The choice of a particular method of management is based on (1) the organizational structure of railways, performing in an oligopolistic transport market, (2) the decision to split the whole railway activity in homogeneous units, and (3) an eventual involvement of the private

sector. It is explained how the fundamental financial indices of a company (in terms of costs, yields, revenues-expenses, productivity) affect managerial decisions. Management is usually correlated with planning and particularly with Business Plans and Project Management. The various issues related to management of railway infrastructure, such as level of infrastructure charges, outsourcing, reduction of maintenance expenses, and attraction of funds for modernization are discussed. Management of rail passenger considers passengers' exigencies (through regular marketing and advertising campaigns) and must make an important decision whether to increase traffic or make a profit. Traditional pricing strategies can be combined with yield management techniques in order to achieve both a higher load factor and increased revenues. However, no managerial decision can ignore the various elasticities in relation to other transport modes. Management of freight should overcome weaknesses such as low average speed and difficulty of door-to-door transport and focus on products suitable for rail transport. Rail freight should be incorporated as a component of the logistics chain and adopt flexible commercial and pricing strategies, similar to those adopted by competitors of railways.

Defining Railway Management and Differentiating it From Management (in its General Sense)

A Definition of Management

Many definitions of management have been suggested over the years so as to respond to the demands of various sectors of the economy and to the needs that management is called to address. However, there are certain underlying characteristics that management encompasses: (1) recognizing and understanding a more or less human activity, (2) defining goals and objectives, (3) setting a plan of successive and interactive steps to be followed, (4) deciding and selecting the most appropriate financial and human resources, and (5) following, controlling, measuring as well as modifying procedures at each step of the activity.

It seems that there is no consensus over whether management constitutes a science or whether it is just an art. These different views stem from the fact that management requires not only a good understanding of a complex problem or system but also other essential qualities such as imagination, intuition, and forecasting abilities of future (and difficult to predict) events and situations, and in some cases even luck.

Managing Railways: Dealing With a Heavy and Rigid Industry

Railways made their appearance in the early 1800s as revolutionary technology at the time, promising to increase traveling speeds and reduce travel times. Before the era of railways, land transport of both people and goods was made possible by walking short and long distances and by horse power, with an average traveling speed at 5–10 km/h worldwide. Railways are based on the guided movement of the wheels of successive wagons on two rails through a metal-to-metal contact. This fact permitted railways to achieve speeds of 125–200 km/h during the 19th century, of 300 km/h in 1989, of 350 km/h in 2020.
